In abandoning the theory of ideas—that is to say, the theory of figures and numbers, the possessions of universal mind, eternally existent out of space and time, which figures and numbers when they pass into space and time as the heritage of finite minds are regarded as things—Speusippus had the approval, as of the Platonists generally, so also of Aristotle. But, whereas the new scholarch, confining himself to the detailed examination of natural kinds, attempted no comprehensive explanation of the universe, Aristotle held that a theory of its origin, its motions, and its order was a necessary adjunct to the classificatory sciences; and in nearly all his references to Speusippus he insists upon this fundamental difference of procedure. Conceiving that the motions of the universe and its parts are due to the desire which it and they feel towards the supreme external mind and its several thoughts, so that the cosmical order planned by the divine mind is realized in the phenomenal universe, Aristotle thus secures the requisite unification, not indeed of mind and matter, for mind and matter are distinct, but of the governing mind, the prime unmoved movent, since it and its thoughts are one. Contrariwise, when Speusippus distinguishes One, Good, and Mind, so that Mind, not as yet endowed with an orderly scheme, adapts the initial One to particular Goods or ends, his theory of nature appears to his rival "episodical," *i.e.* to consist of a series of tableaux wanting in dramatic unity, so that it reminds him of Homer's line—οὐκ ἀγαθὸν πολυκοιρανίη· εἷς κοίρανος ἔστω.

Speusippus and his contemporaries in the school exercised an important and far-reaching influence upon Academic doctrine. When they, the immediate successors of Plato, rejected their master's ontology and proposed to themselves as ends mere classificatory sciences which with him had been means, they bartered their hope of philosophic certainty for the tentative and provisional results of scientific experience. Xenocrates indeed, identifying ideal and mathematical numbers, sought to

[1] That Plato did not neglect, but rather encouraged, classificatory science is shown, not only by a well-known fragment of the comic poet Epicrates, which describes a party of Academics engaged in investigating, under the eye of Plato, the affinities of the common pumpkin, but also by the *Timaeus*, which, while it carefully discriminates science from ontology, plainly recognizes the importance of the study of natural kinds.

shelter himself under the authority of Plato; but, as the Xenocratean numbers, though professedly ideal as well as mathematical, were in fact mathematical only, this return to the Platonic terminology was no more than an empty form. It would seem, then, that Academic scepticism began with those who had been reared by Plato himself, having its origin in their acceptance of the scientific element of his teaching apart from the ontology which had been its basis. In this way, and, so far as the present writer can see, in this way only, it is possible to understand the extraordinary revolution which converted Platonism, philosophical and dogmatic, into Academicism, scientific and sceptical. It is as the official representative of this scientific and sceptical departure that Speusippus is entitled to a place in the history of philosophy.

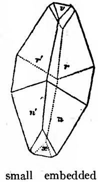
SPEY, a river in the Highlands of Scotland. It rises in Mt Clach-a-Cheannaiche in the north of Lochaber, in Inverness-shire, at a height of 1497 ft. above the sea. A mile from its source it forms the small Loch Spey, and 31 m. lower down it expands into the larger Loch Inch. After crossing the boundary of Elginshire, below Grantown, it pursues an extremely serpentine course, as far as Craigellachie, where it begins to flow due northwards, becoming wholly a Moray stream as it approaches Fochabers, and falling by several mouths into the Moray Firth at Kingston. Its total length is about 110 m. It is the most rapid river in Scotland and is nowhere properly navigable, though at Speymouth in its lowest reaches some ship-building has been intermittently carried on. The strength of its current is due partly to its lofty origin, and partly to the volume of water contributed by numberless affluents from the mountainous regions of its birth. The more important tributaries are, on the left, the Markie, Calder, Dulnain, Tulchan, Ballintomb and Rothes and, on the right, the Mashie, Truim, Tromie, Feshie, Nethy, Avon, Fiddich and Mulben. Its area of drainage is 1300 sq. m. At certain points the stream attains a considerable width, as at Alvie, where it is 150 ft. wide, and at Kingussie, where its width is from 80 to 100 ft. From below Craigellachie, and especially on the low-lying coast-land, pools or stretches of fair size become frequent. For beauty of scenery Strathspey holds its own with any of the great valleys of Scotland. As a salmon river the Spey yields only to the Tay and Tweed. It passes many interesting spots in its long career, such as Laggan; Cluny Castle, the seat of Cluny Macpherson; Craig Dhu, the "black rock," and Kingussie. It flows past the pine forests of Rothiemurchus; Granton, the capital of Strathspey; Cromdale, where the clansmen suffered defeat at the hands of William III.'s troops in 1690; Ballindalloch, with a splendid Scottish baronial castle, the seat of the Macpherson-Grants; and Charlestown of Aberlour and its fine cataract.

SPEZIA, a city of Liguria, Italy, in the province of Genoa, 56 m. S.E. of that town by rail, 49 ft. above sea-level. Pop. (1906), 41,773 (town); 75,756 (commune); in 1861 only 11,556. It is the chief naval harbour of Italy, having been adopted as such in 1861. The Bay of Spezia is sheltered from all except southerly winds, and on its western shore are numerous openings, which afford perfectly safe anchorage in all weathers. The entrance is protected by forts, while a submarine embankment, 2 m. long, renders it secure. The arsenal consists of three departments, the principal of which is 3937 ft. long, with an average width of 2460 ft. The chief basin is 23 acres in extent, and the second—connected with the first by a canal 91 ft. wide—36 acres. Both basins have an average depth of between 33 and 35 ft. The second basin gives access to the docks, of which there are six; two 390 ft. long, two 420 ft. long, one 500 ft. long, and one 650 ft. long. The establishment of San Vito is devoted entirely to the production of artillery; that of San Bartolomeo is exclusively used for electrical works and the manufacture of submarine weapons, especially torpedoes. The arsenal was constructed by General Chiodo (d. 1870), whose statue rises at the entrance, and near it are the naval barracks and hospital. Though the town itself, with the barracks and military hospital as its principal buildings, presents little to attract the foreign visitor, the beauty of the gulf and of the neighbouring country has brought Spezia into some repute as a winter resort, and it is also visited in summer for sea-bathing. The walls and gates of the old city are for the most part destroyed. The opening of a railway across the Apennines (there is a branch leaving the coast line at Vezzano, and joining the line from Sarzana at S. Stefano di Magra), placed Spezia in communication with Parma and the most fertile regions of the Po valley, and so stimulated commerce that a new commercial port to the east of the city was built. This harbour consists of a broad quay with 657 ft. of wharfage, and of a mole 1639 ft. long with 984 ft. of wharfage. The basin of the harbour is about 26 ft. deep. A branch railway connects the wharves directly with the main line. Since the opening of the new port the traffic has considerably increased, and it exports oil, pig-lead, silver, flour, wine, marble and sandstone for paving purposes, while it imports quantities of coal, iron, cereals, phosphates, timber, pitch, petroleum, and mineral oils. The import of coal in 1906 was 439,494 tons, being nearly double the average for 1901–1905. The tonnage of vessels entered was over 600,000, an increase of about 25% on that of 1905. Several important industrial establishments lie along the bay, including large lead and silver works at Pertusola (see Lerici), submarine cable works, a shipyard at Muggiano for the construction of mercantile vessels up to 10,000 tons, a branch of the Vickers Terni works for armour plate, several motorboat works, brick and tile works, &c.

The origin of Spezia is doubtful; but it probably rose after the destruction of Luna. Sold by one of the Fieschi in 1276 to Genoa, the town was fortified by its new possessors and made the seat of a governor of some importance. It became a city in the 16th century. The idea of making the Gulf of Spezia a great naval centre was first broached by Napoleon I.

SPHAERISTERIUM (Gr. σφαιριστήριον, σφαῖρα, ball), the term in Classic architecture given to a large open space connected with the Roman thermae, for exercise with balls after the bather had been anointed; they were also provided in the Roman villas.

SPHENE, a mineral consisting of calcium titano-silicate, $CaTiSiO_5$, crystallizing in the monoclinic system. The crystals vary considerably in habit, but are generally thin and wedge-shaped; hence the name sphene, from the Greek σφήν (a wedge), given by R. J. Haüy in 1801. The earlier name titanite, given by M. H. Klaproth in 1795, is also in common use. Twinning on the ortho-pinacoid is not uncommon. The colour is green, yellow, brown or black, and the lustre resinous to adamantine; crystals are transparent to opaque. The hardness is $5\frac{1}{2}$, and the specific gravity 3·5. The refractive indices and the optic axial angle vary considerably with the colour of the light: the dispersion of the optic axes is inclined, and the interference figure seen in convergent light between crossed nicols is very characteristic of the mineral. Sphene is sometimes cut as a gem-stone, though it is rather too soft to stand much wear; owing to its high dispersive power it gives brilliant flashes of prismatic colours. As small embedded crystals, sphene has a wide distribution as an accessory constituent of many kinds of igneous rocks (granite, syenite, trachyte, phonolite, &c.), and also of gneiss, schist and crystalline limestone. Sharply-developed, transparent, pale green crystals are frequently associated with adularia, asbestos and quartz in the crystal-lined crevices of the schists of the Swiss and Tyrolese Alps. Large, rough and dark-coloured crystals are found at Arendal and Kragerö in Norway, and in granular limestone at Diana in New York and Eganville in Ontario. A greyish, compact and impure variety of sphene, known as



"leucoxene," frequently occurs in basic igneous rocks as an alteration product of ilmenite and rutile. (L. J. S.)

SPHENODON, or TUATARA. *Sphenodon* s. *Hatteria* (called by Gray after Hatter), with one species, *S. punctatum*, is the sole surviving member of the whole group of *Rhynchocephalia* (*q.v.* under REPTILES, *Fossil*). It is one of the few reptiles inhabiting New Zealand; formerly common on the main islands, now restricted to some of the small, uninhabited islands in the Bay of Plenty, where these last "living fossils" enjoy the protection of the government. The Maoris call it *ruatara, tuatete or tuatara*, the latter meaning "having spines." This creature represents an almost ideally generalized type of reptile. The total length of large males is more than two feet, but mature females are scarcely half this size. In general appearance they much resemble the *Agamidae*, especially *Uromastix*, or *Physignathus*, with the massive head, the chisel-shaped front teeth, short legs and erectile crest of cutaneous spines on the head and along the mid-line of the trunk and tail, whilst the rest of the dark olive-green skin is granular, with yellowish specks. But the Agamoid resemblance is only skin-deep, and only the tyro can confound them with any group of Lacertilia. At the same time it is probable that *Sphenodon* stands near the ancestral root of the Lacertilia, before these divided into geckos, chameleons, and lizards proper. The development of this animal has been first studied by G. B. Howes, who quotes the literature bearing upon the whole subject. A good account of the habits of the tuatara has been given by Newman. They live upon animals, but these are only taken when alive and moving about, *e.g.* fish, worms, insects. Sluggish in their habits, they sleep during the greater part of the day in their self-dug burrows, and are very fond of lying in the water, and they remain below for hours without breathing. Each individual excavates its own hole, a tunnel leading into a roomy chamber, lined with grass and leaves; part of the habitation is shared socially by a family of petrels, which is said to occupy usually the left side, whilst the tuatara itself lives a solitary life. The male croaks or grunts much during the pairing season; the hard-shelled, long-oval eggs, about 28 mm. long, are laid in holes in the sand, about ten in one nest, from November to January or February. They contain nearly ripe embryos in the following August, but they are not hatched until about thirteen months old; in the meantime they seem to undergo a kind of hibernation, their nasal chambers becoming blocked with proliferating epithelium, which is resolved shortly before hatching during the southern summer. In spite of their imposing, rather noble appearance, when, with their heads erect, they calmly look about with their large quiet eyes, they are dull creatures, but they bite furiously.

SPHERE (Gr. σφαῖρα, a ball or globe), in geometry, the solid or surface traced out by the revolution of a semicircle about its diameter; this is essentially Euclid's definition;[1] in the modern geometry of surfaces it is defined as the quadric surface passing through the circle at infinity. Every point is equidistant from a fixed point within the surface; this point is the "centre," the constant distance the "radius," and any line through the centre and intersecting the sphere is a "diameter." All sections of the sphere are necessarily circles; if the cutting plane contains the centre, the section is said to be "meridional," the curve of intersection is a "great circle," and the solid cut off a "hemisphere." If the plane does not contain the centre, the curve of intersection is a "small circle," and the solid cut off is a "segment." "Great" circles may also be defined as circles on a sphere which pass through the extremities of a diameter; they are familiar as the meridians or lines of longitude of geographers; lines of latitude are "small-circles." The shortest distance between two points on a sphere is the arc of the great circle containing the points. This proposition is the basis of the "great circle sailing" of navigators, and the arc of the great circle is called the "rhumb-line" or "loxodromic curve." The determination of the shortest distance between two small circles on a sphere is given in the article VARIATIONS, CALCULUS OF. The extremities of the diameter perpendicular to a small circle are called the "poles" of that circle, and the distance from the pole to the circle, measured by the arc of the great circle through the pole, is the "polar distance" of the small circle. The solid enclosed by a small circle and the radii vectores from the centre of the sphere is a "spherical sector"; and the solid contained between two spherical sectors standing on copolar small circles is a "spherical cone." A "spherical sector" and "spherical cone" may be also regarded as the solids of revolution of a circular sector about one of its bounding radii, and about any other line through the vertex respectively. The solid intercepted between two parallel planes is a "zone."

[1] The surfaces formed by revolving a circle about any chord also received attention at the hands of the Greeks. According to Heron and Geminus they were discussed under the name *spire* by Perseus (*c.* 200–100 B.C.), their sections were termed *spiral sections*, and are probably the same as the *hippopede* of Eudoxus. The surface and solid traced by the revolution of the lesser segment of a circle is termed a "spindle." An "anchor ring" or "tore" results when a circle revolves about an axis in its plane.

The geometry of the sphere was studied by the Greeks; Euclid, in book xii. of his *Elements*, discusses various properties of the sphere, and in book xiii. he shows how to inscribe the five regular polyhedra within it. But with the sole exception of proving that the volumes of spheres are in the triplicate ratio of their diameters, a theorem probably due to Eudoxus, no mention is made of its mensuration. This subject was investigated by Archimedes, who, by his "method of exhaustions," derived the principal results. He showed that the surface of a segment is equal to the area of the circle whose radius equals the distance from the vertex to the base of the segment; that the surface of the entire sphere is equal to the curved surface of the circumscribing cylinder, and to four times the area of a great circle of the sphere; and that the volume is two-thirds that of the circumscribing cylinder. To Zenodorus (*c.* 200–100 B.C.) is due the important problem in maxima and minima that for a given surface the sphere is the solid of maximum volume. Calling the radius r, and denoting by π the ratio of the circumference to the diameter of a circle, the volume is $\frac{4}{3}\pi r^3$, and the surface $4\pi r^2$.

Archimedes gave his results in the treatise Περὶ τῆς σφαίρας καὶ τοῦ κυλίνδρου: he left unfinished the problem of dividing a sphere into segments whose volumes are in a given ratio. A solution by means of the parabola and hyperbola was given by Dionysodorus of Amisus (*c.* 1st century B.C), and a similar problem—to construct a segment equal in volume to a given segment, and in surface to another segment—was solved by the Arabian mathematician and astronomer, Al Kuhi.

In analytical geometry, the equation to the sphere takes the forms $x^2+y^2+z^2=a^2$, and $r=a$, the first applying to rectangular Cartesian co-ordinates, the second to polar, the origin being in both cases at the centre of the sphere. If the centre be (α, β, γ), the Cartesian equation becomes $(x-\alpha)^2+(y-\beta)^2+(z-\gamma)^2=a^2$; consequently the general equation is $x^2+y^2+z^2+2Ax+2By+2Cz+D=0$, and it is readily shown that the co-ordinates of the centre are $(-A, -B, -C)$, and the radius $A^2+B^2+C^2-D$. A sphere can therefore be described so as to satisfy four given conditions. Systems of spheres have characters analogous to those of systems of circles. If r, r_1 be the radii of two spheres, d the distance between the centres, and ϕ the angle at which they intersect, then $d^2=r^2+r_1^2+2rr_1\cos\phi$; hence $2rr_1\cos\phi=d^2-r^2-r_1^2$. This function is named the "power" of the two spheres, and it is important in the investigation of systems of spheres. If the sphere r_1 degenerate to a point, the function $2rr_1\cos\phi$ has the limit d^2-r^2; this is the square of the tangent to the sphere from the point, and is named the "power of the sphere at the point," or the "power of the point with respect to the sphere." Two spheres intersect in a plane, and the equation to a system of spheres which intersect in a common circle is $x^2+y^2+z^2+2Ax+D=0$, in which A varies from sphere to sphere, and D is constant for all the spheres, the plane yz being the plane of intersection, and the axis of x the line of centres. Corresponding to the radical centre of three circles, it may be shown that four spheres have a radical centre, *i.e.* that there exists a point such that the tangents from this point to the four spheres are equal, and that with this point as centre, and the length of the tangent as radius, a sphere may be described which cuts the four spheres at right angles; this "orthotomic" sphere corresponds to the orthogonal circle of a system of circles.

The investigation of triangles and other figures drawn upon the surface of a sphere is all-important in the sciences of astronomy, geodesy and geography. In astronomy, we are principally concerned with the orientation of points on a sphere—the so-called celestial sphere—with regard to certain planes and points within the sphere; this subject is treated in the article ASTRONOMY (*Spherical*). In "geodesy," and the cognate subject "figure of the earth," the matter of greatest moment with regard to the sphere is the determination of the area of triangles drawn on the surface of a sphere—the so-called "spherical triangles"; this is a branch of trigonometry, and is studied under the name of spherical trigonometry. In mathematical geography the problem of representing the surface of a sphere on a plane is of fundamental importance; this subject is treated in the article MAP.

SPHERES, MUSIC OF THE, in Pythagorean philosophy, the harmony produced by the heavenly bodies in their orbits, inaudible to human ears. Pythagoras (cf. Arist. *de Caelo*, ii. 9) held that the movements of stars were governed by fixed laws which could be expressed in numbers according to the numbers which give the harmony of sounds (see PYTHAGORAS, *ad fin.*). It is this theory to which Shakespeare alludes in *The Merchant of Venice* (Act. v. i. seq.: "such harmony is in immortal souls, but . . . we cannot hear it"). According to Gomperz (*Greek Thinkers*, i. 118, Eng. trans.) "there was nothing fanciful in the Pythagorean doctrine except only the belief that the differences of velocity in the movements of the stars were capable of producing a harmonious orchestration and not merely sounds of varying pitch."

SPHERES OF INFLUENCE. "Spheres of influence," "spheres of action," "spheres of interest," "zones of influence," "field of operations," "Machtsphäre," "Interessensphäre," are phrases in international law which have come into use to describe regions as to which nations have agreed that one or more of them shall have exclusive liberty of action. These phrases became common after 1882, when the "scramble for Africa" began, to describe diplomatic arrangements with respect to it. Some definitions may be quoted—when secretary of state for the colonies, Lord Knutsford, replying to a deputation in 1890, said: "'Sphere of action' is a term I do not wish to define now; but it amounts to this: we should not allow the Portuguese, Germans, or any foreign nation or republic to settle down and annex the territory" (quoted in Keane's *Compendium of Geography*, i. 21). "The term 'sphere of influence' implies an engagement between two states that one of them will abstain from interfering or exercising influences within certain territories which, as between the contracting parties, are reserved for the operation of the other" (Ilbert, *Government of India*, 2nd ed., p. 370). "Unter 'Interessensphäre' oder 'Machtsphäre' versteht man nämlich das auf Grund von Vereinbarungen unter den betheiligten Kolonialstaaten abgegrenzte Gebiet, innerhalb dessen ein Staat ausschliesslich berechtigt ist, seine koloniale Herrschaft durch Besitzergreifung oder Abschluss von Protectoratsverträgen zu begründen, oder doch einen für die in diesem Gebiete vorhandenen Völkerschaften massgebenden politischen Einfluss auszuüben" (Stengel, *Die deutschen Schutzgebiete*, p. 18). "The term 'sphere of influence or sphere of interest' has been given an extended meaning by recent developments. Formerly it was used to signify a region wherein a nation, through its citizens, had acquired commercial or industrial interests without having asserted any political protectorate or suzerainty. To-day, as used in China and elsewhere, the term applies rather to a region pre-empted for further exploitation and possibly for political control" (Dr Reinisch's *Politics*, pp. 60, 61). "A portion of a non-Christian or uncivilized country which is the subject of diplomatic arrangements between European states, but has not yet developed into a protectorate" (Jenkyn's *British Rule and Jurisdiction beyond the Seas*). See also Hall, 6th ed., 129.

Definitions.

The reasons for making these arrangements are to be explained partly by reference to the history of international law as to occupation. The Roman jurists recognized certain "natural modes" of acquiring property, in particular *traditio* and *occupatio*. The doctrines which the Roman jurists had worked out as to acquisition of private property by occupation were applied to the appropriation by states or their subjects of vacant lands (*res nullius*), including lands in the possession of barbarous tribes. "Quod enim nullius est, id ratione naturali occupanti conceditur" (*Institutes*, ii. 1–12). The Roman law required the *animus domini*—there must be seizure for and on behalf of the owner. There must be "*apprehensio.* Apiscimur possessionem corpore et animo, neque per se animo aut per se corpore" (*Dig.* xli. 2–3). Professing to act on these doctrines, and relying also on an assumed right on the part of Christian nations to subdue obdurate non-Christian communities, the navigators and explorers of the 15th and 16th centuries made exorbitant claims. Having occupied certain points on the coast-line, they claimed to have occupied a whole island or continent (De Martens i. 462). They made vast claims under Papal bulls; for example, under the bull of Nicholas V. of 1454, and the bull of Alexander VI. of 1494, which assigned to the Portuguese the empire of Guinea just discovered. It was one of Grotius's services to diffuse sounder ideas, and to point out that Roman law gave no support to these pretensions: "Invenire non illud est oculis usurpare, sed apprehendere" (*Mare liberum*, c. 2). He insisted that "occupatio autem publica eodem modo fit quo privata territoria sunt ex occupationibus populorum ut privata dominia ex occupationibus singulorum." In recent times the old doctrine that discovery without occupation confers an independent right to the land so discovered of any extent is discredited. The tendency is to insist on actual occupation as a condition of legitimate possession or sovereignty (see correspondence between Great Britain and Portugal, State Papers 79, p. 1062), and to treat the discoverer's right as merely inchoate. Thus, in opening the conference at Berlin in 1884, Prince Bismarck said: "Pour qu'une occupation soit considérée comme effective, il est, de plus, à désirer que l'acquéreur manifeste, dans délai raisonnable, par des institutions positives, la volonté et le pouvoir d'y exercer ses droits et de remplir les devoirs qui en résultent." This doctrine is recognized in articles 34 and 35 of the General Act of Berlin, the former of which states that "any Power which henceforth takes possession of a tract of land on the coast of the African continent outside its possessions, or which being hitherto without such possessions shall acquire them, as well as the Power which assumes a protectorate, shall accompany the respective act with a notification thereof, addressed to the other Signatory Powers of the present act, in order to enable them, if need be, to make good any claim of their own." To a similar effect wrote Lord Salisbury in 1887 with reference to the claims of Portugal in East Africa. "Great Britain considers that it has been admitted in principle by all the parties to the act of Berlin that a claim of sovereignty in Africa can only be maintained by real occupation of the territory claimed; and that the doctrine has been practically applied in the recent Zambezi delimitation (State Papers 79, p. 1063). No paper annexation of territory can pretend to validity as a bar to the enterprise of other nations." At its session at Lausanne, in 1889, the Institut de Droit International adopted the following principles:—

Rights of Discoverer and Occupation.

"Article 1.—L'occupation d'un territoire à titre de souveraineté ne pourra être reconnue comme effective que si elle réunit les conditions suivantes: 1° La prise de possession d'un territoire enfermé dans certaines limites, faite au nom du gouvernement. 2° La notification officielle de la prise de possession. La prise de possession s'accomplit par l'établissement d'un pouvoir local responsable, pourvu de moyens suffisants pour maintenir l'ordre et pour assurer l'exercice régulier de son autorité dans les limites du territoire occupé. Ces moyens pourront être empruntés à des institutions existantes dans le pays occupé. La notification de la prise de possession de fait, soit pour la publication dans la forme qui, dans chaque état, est en usage pour la notification des actes officiels, soit par la voie diplomatique. Elle contiendra la détermination approximative des limites du territoire occupé" (*Annuaire* x. 201).

This development of international law naturally led to arrangements as to "spheres of influence." Nations which had not yet settled or occupied, or established protectorates, in regions contiguous to their existing possessions, were desirous to retain a hold over the former, and proceeded to enter into treaties defining the spheres of influence.

The following are some of the chief treaties by which such spheres are defined:—

Great Britain and Portugal as to Africa, August 20, 1890, November 14, 1890 and June 11, 1891. Great Britain and France as to Upper Niger, January 20, 1891; November 15, 1893, as to Lake Chad. Great Britain and France as to Siam, January 15, 1896. The two governments engage to one another "that neither of them will, without the consent of the other in any case or under any pretext, advance their armed forces into the regions, &c." They also engage not to acquire within this region any special privilege or advantage which shall not be enjoyed in common, or equally open to Great Britain and France or their nationals and dependants. Great Britain and Italy as to Africa, April 15, 1891; May 5, 1894, as to region of the Gulf of Aden. Congo and Portugal, May 25, 1891, as to "sphères de souveraineté et d'influence" in the region of Lunda. Great Britain, Belgium and Congo, May 12, 1894, as to the sphere of influence of the independent Congo State. Great Britain and Germany, July 1, 1890 and November 15, 1893, as to East and Central Africa. Great Britain and Russia as to the spheres of influence to the east of Lake Victoria in the region of the Pamirs, March 11, 1895.

As an example of the promises or engagements in such treaties may be quoted that between Great Britain and Portugal of the 20th of August 1890. Portugal engages that the territory of which the limits are defined in article 3 shall not, without the consent of Great Britain, be transferred to any other power. In the treaty between the same powers of the 14th of November 1890 it is stipulated that neither power will make, tender, accept protectorates, or exercise any act of sovereignty, &c. Sometimes a treaty defining spheres of influence declares that such and such territory shall be neutral.

In the treaty of delimitation between France and Germany of the 15th of March 1894, the line of demarcation of the zones of influence of the two states in the region of Lake Chad is drawn, and they agree to exercise no political influence in such spheres. Each of the states agrees (art. 2) to acquire no territory, to conclude no treaties, to accept no rights of sovereignty, or protectorate, and not "gêner ou de contester l'influence de l'autre Puissance dans la zone qui lui est reservée."

Being the result of treaties, arrangements as to spheres of influence bind only the parties thereto. As Mr Olney, in his correspondence with Lord Salisbury in regard to Venezuela, remarked: "Arrangements as to spheres of influence are new departures, which certain great European Powers have found necessary and convenient in the course of their division among themselves of great tracts of the continent of Africa, and which find their sanction solely in their reciprocal obligations" (United States No. 2, 1896, p. 27).

Some treaties expressly declare that the arrangement shall not affect the rights of other powers (Stoerck, *Recueil*, xvi. p. 932). No doubt, however, the tendency is for spheres of influence to become protectorates. It may be mentioned that Germany and Holland have concluded a treaty (Dec. 21, 1897) by which the latter agrees to extradite German criminals in spheres of influence. By an agreement of the 12th of May 1894 between Great Britain and the Congo State, the former granted to the latter a lease of territories comprised within the sphere of influence laid down in the Anglo-German agreement of the 1st of July 1890 (19 *Hertslet*, p. 179).

Somewhat akin to the rights of a state in a sphere of influence are those possessed by Germany in the zone surrounding the protectorate of Kiaochow under the treaty of the 6th of March 1898, and the rights obtained under treaties with China that certain provinces shall not be alienated.

Somewhat similar arrangements as to ports of the sea are not unknown. Grotius in his *Mare liberum* says: "Illud interim fatemur, potuisse inter gentes aliquas convenire, ut capti in maris hac vel illa parte, hujus aut illius reipublicae judicium subirent, atque ita ad commoditatem distinguendae jurisdictionis in mari fines describi, quod ipsos quidem eam sibi legem ferentes obligat, at alios populos non item; neque locum cujus proprium facit, sed in personas contrahentium jus constituit" (c. 5).

The best known example of a claim to a sphere of influence, which is not the result of any treaty, is the Monroe doctrine, first broached by President Monroe in 1823. The Romans had their equivalent to the Monroe doctrine; they forbade any Asiatic king entering Europe and conquering any part of it; the breach of this rule was their chief grievance against Mithradates (Montesquieu, *De la Grandeur et de la décadence des romains*, (c. 6).

Claims somewhat similar to those relating to spheres of influence have been put forward as against the whole world, in virtue of the right of continuity or the doctrine of the hinterland. Sometimes it is called the "doctrine of contiguity," or "droit de vicinité, de priorité, de préemption ou d'enclave." He who occupies a part of a well-defined close or *fundus*, a parcel of land with artificial or natural boundaries, which enables him to control the whole area, may be said to occupy it. He need not be present everywhere, or enter on every part of it: "Sufficit quamlibet partem ejus fundi introire, dum mente et cogitatione hac sit, uti totum fundum usque ad terminum velit possidere" (*Dig.* xli. 2, 3). In virtue of a supposed analogy to such occupation, it has been said that the occupation of the mouth of a river is constructive occupation of all its basin and tributaries, and that the occupation of part of a territory extends to all the country of which it forms physically a part. A state, having actually occupied the coast, may claim to reserve to itself the right of occupying from time to time territory lying inland (hinterland). In the discussions as to the western boundary of Louisiana between the commissions of the United States and Spain, as to Oregon, as to the claims of the Portuguese in East Africa, and as to the boundaries of Venezuela, the question of the extent of the rights of the discoverer and occupier came up. Portugal actually claimed all territory lying between her African possessions. It has been urged that the subsequent settlement within a reasonable time of the mouth of a river, "particularly if none of its branches had been explored prior to such discovery, gave the right of occupation, and ultimately of sovereignty, to the whole country drained by such river and its several branches." Another form of the same doctrine is, that the occupier of a part of the sea-coast thereby acquires rights "extending into the interior of the country to the sources of the rivers emptying within that coast, to all their branches, and the country they cover" (Twiss, *Laws of Nations in Time of Peace*, p. 170; Twiss, *Oregon Question*, p. 245; Bluntschli, s. 282; Phillimore, *Commentaries*, p. 236; Westlake, *International Law*, pt. i. p. 128). Lord Salisbury referred to "the modern doctrine of hinterland with its inevitable contradictions" (United States, No. 2, 1896, p. 12). Certainly it is inconsistent with the doctrine, more and more received in recent times, that effective possession is necessary to found a title to sovereignty or control. It is akin to the extravagant claims of the early Portuguese and Spanish navigators to territory on which they had never set foot or eyes. The doctrine of the hinterland is likely to become less important, now that Africa has been parcelled out.

Hinterland.

SPHERICAL HARMONICS, in mathematics, certain functions of fundamental importance in the mathematical theories of gravitation, electricity, hydrodynamics, and in other branches of physics. The term "spherical harmonic" is due to Lord Kelvin, and is primarily employed to denote either a rational integral homogeneous function of three variables x, y, z, which satisfies the differential equation

$$\nabla^2 V \equiv \frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = 0,$$

known as Laplace's equation, or a function which satisfies the differential equation, and becomes a rational integral homogeneous function when multiplied by a power of $(x^2+y^2+z^2)^{\frac{1}{2}}$.

Of all particular integrals of Laplace's equation, these are of the greatest importance in respect of their applications, and were the only ones considered by the earlier investigators; the solutions of potential problems in which the bounding surfaces are exactly or approximately spherical are usually expressed as series in which the terms are these spherical harmonics. In the wider sense of the term, a spherical harmonic is any homogeneous function of the variables which satisfies Laplace's equation, the degree of the function being not necessarily integral or real, and the functions are not necessarily rational in x, y, z, or single-valued; when the term spherical harmonic is used in the narrower sense, the functions may, when necessary, be termed ordinary spherical harmonics. For the treatment of potential problems which relate to spaces bounded by special kinds of surfaces, solutions of Laplace's equation are required which are adapted to the particular boundaries, and various classes of such solutions have thus been introduced into analysis. Such functions are usually of a more complicated structure than ordinary spherical harmonics, although they possess analogous properties. As examples we may cite Bessel's functions in connexion with circular cylinders, Lamé's functions in connexion with ellipsoids, and toroidal functions for anchor rings. The theory of such functions may be regarded as embraced under the general term harmonic analysis. The present article contains an account of the principal properties of ordinary spherical harmonics, and some indications of the nature and properties of the more important of the other classes of functions which occur in harmonic analysis. Spherical and other harmonic functions are of additional importance in view of the fact that they are largely employed in the treatment of the partial differential equations of physics, other than Laplace's equation; as examples of this, we may refer to the equation $\frac{\partial u}{\partial t}=k\nabla^2 u$, which is fundamental in the theory of conduction of heat and electricity, also to the equation $\frac{\partial^2 u}{\partial t^2}=k\nabla^2 u$, which occurs in the theory of the propagation of aerial and electro-magnetic waves. The integration under given conditions of more complicated equations which occur in the theories of hydro-dynamics and elasticity, can in certain cases be effected by the use of the functions employed in harmonic analysis.

1. *Relation between Spherical Harmonics of Positive and Negative Degrees.*—A function which is homogeneous in x, y, z, of degree n in those variables, and which satisfies Laplace's equation

$$\frac{\partial^2 V}{\partial x^2}+\frac{\partial^2 V}{\partial y^2}+\frac{\partial^2 V}{\partial z^2}=0, \text{ or } \nabla^2 V=0, \qquad (1)$$

is termed a solid spherical harmonic, or simply a spherical harmonic of degree n. The degree n may be fractional or imaginary, but we are at present mainly concerned with the case in which n is a positive or negative integer. If x, y, z be replaced by their values $r \sin\theta \cos\phi$, $r\sin\theta\sin\phi$, $r\cos\theta$ in polar co-ordinates, a solid spherical harmonic takes the form $r^n f_n(\theta,\phi)$; the factor $f_n(\theta,\phi)$ is called a surface harmonic of degree n. If V_n denote a spherical harmonic of degree n, it may be shown by differentiation that $\nabla^2(r^m V_n) = m(2n+m+1)r^{m-2}V_n$, and thus as a particular case that $\nabla^2(r^{-2n-1}V_n)=0$; we have thus the fundamental theorem that from any spherical harmonic V_n of degree n, another of degree $-n-1$ may be derived by dividing V_n by r^{2n+1}. All spherical harmonics of negative integral degree are obtainable in this way from those of positive integral degree. This theorem is a particular case of the more general inversion theorem that if $F(x, y, z)$ is any function which satisfies the equation (1), the function

$$\frac{1}{r}F\left(\frac{x}{r^2}, \frac{y}{r^2}, \frac{z}{r^2}\right)$$

also satisfies the equation.

The ordinary spherical harmonics of positive integral degree n are those which are rational integral functions of x, y, z. The most general rational integral function of degree n in three letters contains $\frac{1}{2}(n+1)(n+2)$ coefficients; if the expression be substituted in (1), we have on equating the coefficients separately to zero $\frac{1}{2}n(n-1)$ relations to be satisfied; the most general spherical harmonic of the prescribed type therefore contains $\frac{1}{2}(n+1)(n+2)-\frac{1}{2}n(n-1)$, or $2n+1$ independent constants. There exist, therefore, $2n+1$ independent ordinary harmonics of degree n; and corresponding to each of these there is a negative harmonic of degree $-n-1$ obtained by dividing by r^{2n+1}. The three independent harmonics of degree 1 are x, y, z; the five of degree 2 are y^2-z^2, z^2-x^2, yz, zx, xy. Every harmonic of degree n is a linear function of $2n+1$ independent harmonics of the degree; we proceed, therefore, to find the latter.

2. *Determination of Harmonics of given Degree.*—It is clear that a function $f(ax+by+cz)$ satisfies the equation (1), if a, b, c are constants which satisfy the condition $a^2+b^2+c^2=0$; in particular the equation is satisfied by $(z+\iota x\cos\alpha+\iota y\sin\alpha)^n$. Taking n to be a positive integer, we proceed to expand this expression in a series of cosines and sines of multiples of α; each term will then satisfy (1) separately. Denoting $e^{\iota\alpha}$ by k, and $y+\iota x$ by t, we have

$$(z+\iota x\cos\alpha+\iota y\sin\alpha)^n=\left(z+\frac{1}{2}kt+\frac{z^2}{2kt}-\frac{r^2}{2kt}\right)^n$$

which may be written as $(2kt)^{-n}\{(z+kt)^2-r^2)\}^n$. On expansion by Taylor's theorem this becomes

$$(2kt)^{-n}\sum_{0}^{2n}\frac{k^s t^s}{s!}\frac{\partial^s}{\partial z^s}(z^2-r^2)^n,$$

the differentiation applying to z only as it occurs explicitly; the terms involving $\cos m\alpha$, $\sin m\alpha$ in this expansion are

$$\frac{1}{2^n}\cos m\alpha\left\{\frac{(y+\iota x)^m}{(n+m)!}\frac{\partial^{n+m}}{\partial z^{n+m}}(z^2-r^2)^n+\frac{(y+\iota x)^{-m}}{(n+m)!}\frac{\partial^{n-m}}{\partial z^{n-m}}(z^2-r^2)^m\right\}$$

$$i\frac{1}{2^n}\sin m\alpha\left\{\frac{(y+\iota x)^m}{(n+m)!}\frac{\partial^{n+m}}{\partial z^{n+m}}(z^2-r^2)^n-\frac{(y+\iota x)^{-m}}{(n-m)!}\frac{\partial^{n-m}}{\partial z^{n-m}}(z^2-r^2)^m\right\}$$

where $m=1, 2, \ldots n$; and the term independent of α is

$$\frac{1}{2^n n!}\frac{\partial^n}{\partial z^n}(z^2-r^2)^n.$$

On writing

$(y+\iota x)^m=\iota^m r^m(\cos m\phi-\iota\sin m\phi)2\sin^m\theta$, $(y+\iota x)^{-m}=$
$i^{-m}r^{-m}(\cos m\phi+\iota\sin m\phi)\sin^{-m}\theta$

and observing that in the expansion of $(z+\iota x\cos\alpha+\iota y\sin\alpha)^m$ the expressions $\cos m\alpha$, $\sin m\alpha$ can only occur in the combination $\cos m(\phi-\alpha)$, we see that the relation

$$i^m r^m\frac{\sin^m\theta}{(n+m)!}\frac{\partial^{n+m}}{\partial z^{n+m}}(z^2-r^2)^n=i^{-m}r^{-m}\frac{\sin^{-m}\theta}{(n-m)!}\frac{\partial^{n-m}}{\partial z^{n-m}}(z^2-r^2)^n$$

must hold identically, and thus that the terms in the expansion reduce to

$$\frac{1}{(n+m)!}\frac{\iota^m}{2^{n-1}}r^m\cos m\alpha\cos m\phi\sin^m\theta\frac{\partial^{n+m}}{\partial z^{n+m}}(z^2-r^2)^n$$

$$\frac{1}{(n+m)!}\frac{\iota^m}{2^{n-1}}r^m\sin m\alpha\sin m\phi\sin^m\theta\frac{\partial^{n+m}}{\partial z^{n+m}}(z^2-r^2)^n.$$

We thus see that the spherical harmonics of degree n are of the form

$$r^n\,{}^{\cos}_{\sin}\,m\phi\sin^m\theta\frac{d^{n+m}}{d\mu^{n+m}}(\mu^2-1)^n$$

where μ denotes $\cos\theta$; by giving m the values $0, 1, 2 \ldots n$ we thus have the $2n+1$ functions required. On carrying out the differentiations we see that the required functions are of the form

$$A[(x+\iota y)^m\pm(x-\iota y)^m]\left\{z^{n-m}-\frac{(n-m)(n-m-1)}{2.\,2n-1}z^{n-m-2}(x^2+y^2+z^2)\right.$$
$$\left.+\frac{(n-m)(n-m-1)(n-m-2)(n-m-3)}{2.4.2n-1\,.2n-3}z^{n-m-4}(x^2+y^2+z^2)^2 \ldots\ldots\right\} \qquad (2)$$

where $m=0, 1, 2, 3, \ldots n$.

3. *Zonal, Tesseral and Sectorial Harmonics.*—Of the system of $2n+1$ harmonics of degree n, only one is symmetrical about the z axis; this is

$$r^n\frac{1}{2^n n!}\frac{d^n}{d\mu^n}(\mu^2-1)^n;$$

writing

$$P_n(\mu)=\frac{1}{2^n n!}\frac{d^n}{d\mu^n}(\mu^2-1)^n,$$

we observe that $P_n(\mu)$ has n zeros all lying between ± 1, consequently the locus of points on a sphere $r=a$, for which $P_n(\mu)$ vanishes is n circles all parallel to the meridian plane: these circles divide the sphere into zones, thus $P_n(\mu)$ is called the zonal surface harmonic of degree n, and $r^n P_n(\mu)$, $r^{-n-1}P_n(\mu)$ are the solid zonal harmonics of degrees n and $-n-1$. The locus of points on a sphere for which ${}^{\cos}_{\sin}\,m\phi.\sin^m\theta\frac{d^{n+m}}{d\mu^{n+m}}(\mu^2-1)^n$ vanishes consists of $n-m$ circles parallel to the meridian plane, and m great circles through the poles; these circles divide the spherical surface into quadrilaterals or τέσσερα, except when $n=m$, in which case the surface is divided into sectors, and the harmonics are therefore called tesseral, except those for which $m=n$, which are called sectorial. Denoting $(1-\mu^2)^{\frac{1}{2}m}\frac{d^m P_n(\mu)}{d\mu^m}$ by $P_n^m(\mu)$, the tesseral surface harmonics are ${}^{\cos}_{\sin}\,m\phi\,.\,P_n^m(\cos\theta)$, where $m=1, 2, \ldots n-1$, and the sectorial harmonics are ${}^{\cos}_{\sin}\,n\phi\,.\,P_n^n(\cos\theta)$. The functions $P_n(\mu)$, $P_n^m(\mu)$ denote the expressions

$$P_n(\mu)=\frac{(2n)!}{2^n n!\,n!}\left\{\mu^n-\frac{n(n-1)}{2.2n-1}\mu^{n-2}+\frac{n(n-1)(n-2)(n-3)}{2.4.2n-1.2n-3}\mu^{n-4}\dots\right\} \quad (3)$$

$$P_n^m(\mu)=\frac{(2n)!}{2^n n!\,(n-m)!}(1-\mu^2)^{\frac{1}{2}m}\left\{\mu^{n-m}-\frac{(n-m)(n-m-1)}{2.2n-1}\mu^{n-m-2}+\dots\right\} \quad (4)$$

$$P_n^n(\mu)=\frac{(2n)!}{2^n n!}(1-\mu^2)^{\frac{1}{2}n}.$$

Every ordinary harmonic of degree n is expressible as a linear function of the system of $2n+1$ zonal, tesseral and sectorial harmonics of degree n; thus the general form of the surface harmonic is

$$a_0P_n(\mu)+\sum_{m=1}^{n}(a_m\cos m\phi+b_m\sin m\phi)P_n^m(\mu). \quad (5)$$

In the present notation we have

$$(z+\iota x\cos\alpha+\iota y\sin\alpha)^n=r^n\left\{P_n(\mu)+2\sum_{1}^{n}\iota^m\frac{n!}{(n+m)!}P_n^m(\mu)\cos m(\phi-\alpha)\right\}$$

if we put $\alpha=0$, we thus have

$$(\cos\theta+\iota\sin\theta\cos\phi)^n=P_n(\cos\theta)+2\sum_{1}^{n}\iota^m\frac{n!}{(n+m)!}P_n^m(\cos\theta)\cos m\phi,$$

from this we obtain expressions for $P_n(\cos\theta)$, $P_n^m(\cos\theta)$ as definite integrals

$$\left.\begin{aligned}P_n(\cos\theta)&=\frac{1}{\pi}\int_0^\pi(\cos\theta+\iota\sin\theta\cos\phi)^n d\phi\\ \iota^m\frac{n!}{(n+m)!}P_n^m(\cos\theta)&=\frac{1}{\pi}\int_0^\pi(\cos\theta+\iota\sin\theta\cos\phi)^n\cos m\phi d\phi.\end{aligned}\right\} \quad (6)$$

4. *Derivation of Spherical Harmonics by Differentiation.*—The linear character of Laplace's equation shows that, from any solution, others may be derived by differentiation with respect to the variables x, y, z; or, more generally, if

$$f\left(\frac{\partial}{\partial x},\frac{\partial}{\partial y},\frac{\partial}{\partial z}\right)$$

denote any rational integral operator,

$$f\left(\frac{\partial}{\partial x},\frac{\partial}{\partial y},\frac{\partial}{\partial z}\right)V$$

is a solution of the equation, if V satisfies it. This principle has been applied by Thomson and Tait to the derivation of the system of any integral degree, by operating upon $1/r$, which satisfies Laplace's equation. The operations may be conveniently carried out by means of the following differentiation theorem. (See papers by Hobson, in the *Messenger of Mathematics*, xxiii. 115, and *Proc. Lond. Math. Soc.* vol. xxiv.)

$$f_n\left(\frac{\partial}{\partial x},\frac{\partial}{\partial y},\frac{\partial}{\partial z}\right)\frac{1}{r}=(-1)^n\frac{(2n)!}{2^n n!}\frac{1}{r^{2n+1}}\left\{1-\frac{r^2\nabla^2}{2.2n-1}+\frac{r^4\nabla^4}{2.4.2n-1.2n-3}-\dots\right\}f_n(x,y,z) \quad (7)$$

which is a particular case of the more general theorem

$$f_n\left(\frac{\partial}{\partial x},\frac{\partial}{\partial y},\frac{\partial}{\partial z}\right)F(r)=\left\{2^n\frac{d^nF}{d(r^2)^n}+\frac{2^{n-2}}{1!}\frac{d^{n-1}F}{d(r^2)^{n-1}}\nabla^2+\dots+\frac{2^{n-2s}}{s!}\frac{d^{n-s}F}{d(r^2)^{n-s}}\nabla^{2s}+\dots\right\}f_n(x,y,z) \quad (7^1),$$

where $f_n(x, y, z)$ is a rational integral homogeneous function of degree n. The harmonic of positive degree n corresponding to that of degree $-n-1$ in the expression (7) is

$$\left\{1-\frac{r^2\nabla^2}{2.2n-1}+\frac{r^4\nabla^4}{2.4.2n-1.2n-3}-\dots\right\}f_n(x,y,z).$$

It can be verified that even when n is unrestricted, this expression satisfies Laplace's equation, the sole restriction being that of the convergence of the series.

5. *Maxwell's Theory of Poles.*—Before proceeding to obtain by means of (7), the expressions for the zonal, tesseral and sectorial harmonics, it is convenient to introduce the conception, due to Maxwell (see *Electricity and Magnetism*, vol. i. ch. ix.), of the poles of a spherical harmonic. Suppose a sphere of any radius drawn with its centre at the origin; any line whose direction-cosines are l, m, n drawn from the origin, is called an axis, and the point where this axis cuts the sphere is called the pole of the axis. Different axes will be denoted by suffixes attached to the direction-cosines; the cosine $(l_\iota x+m_\iota y+n_\iota z)/r$ of the angle between the radius vector r to a point (x, y, z) and the axis $(l_\iota, m_\iota, n_\iota)$, will be denoted by λ_ι; the cosine of the angle between two axes is $l_\iota l_\gamma+m_\iota m_\gamma+n_\iota n_\gamma$, which will be denoted by $\mu_{\iota\gamma}$. The operation

$$l_\iota\frac{\partial}{\partial x}+m_\iota\frac{\partial}{\partial y}+n_\iota\frac{\partial}{\partial z}$$

performed upon any function of x, y, z, is spoken of as differentiation with respect to the axis $(l_\iota, m_\iota, n_\iota)$, and is denoted by $\partial/\partial h_\iota$. The potential function $V_0=e_0/r$ is defined to be the potential due to a singular point of degree zero at the origin; e_0 is called the strength of the singular point. Let a singular point of degree zero, and strength e_0, be on an axis h_1, at a distance a_0 from the origin, and also suppose that the origin is a singular point of strength $-e_0$; let e_0 be indefinitely increased, and a_0 indefinitely diminished, but so that the product e_0a_0 is finite and equal to e_0; the origin is then said to be a singular point of the first degree, of strength e_1, the axis being h_1. Such a singular point is frequently called a doublet. In a similar manner, by placing two singular points of degree, unity and strength, e_1, $-e_1$, at a distance a_1 along an axis h_2, and at the origin respectively, when e_1 is indefinitely increased, and a_1 diminished so that e_1a_1 is finite and $=e_2$, we obtain a singular point of degree 2, strength e_2 at the origin, the axes being h_1, h_2. Proceeding in this manner we arrive at the conception of a singular point of any degree n, of strength e_n at the origin, the singular point having any n given axes $h_1, h_2, \dots h_n$. If $e_{n-1}\phi_{n-1}(x, y, z)$ is the potential due to a singular point at the origin, of degree $n-1$, and strength e_{n-1}, with axes $h_1, h_2, \dots h_{n-1}$, the potential of a singular point of degree n, the new axis of which is h_n, is the limit of

$$e_{n-1}\phi_{n-1}(x-l_na, y-m_na, z-n_na)-e_{n-1}\phi_{n-1}(x,y,z);$$

when

$$La=0,\ Le_{n-1}=\infty,\ Lae_{n-1}=e_n;$$

this limit is

$$-e_n\left(l_n\frac{\partial\phi_{n-1}}{\partial x}+m_n\frac{\partial\phi_{n-1}}{\partial y}+n_n\frac{\partial\phi_{n-1}}{\partial z}\right),\ \text{or}\ -e_n\frac{\partial}{\partial h_n}\phi_{n-1}.$$

Since $\phi_0=1/r$, we see that the potential V, due to a singular point at the origin of strength e_n, and axes $h_1, h_2, \dots h_n$ is given by

$$V_n=(-1)^n e_n\frac{\partial^n}{\partial h_1\partial h_2\dots\partial h_n}\frac{1}{r}. \quad (8)$$

6. *Expression for a Harmonic with given Poles.*—The result of performing the operations in (8) is that V_n is of the form

$$n!e_n\frac{Y_n}{r^{n+1}},$$

where Y_n is a surface harmonic of degree n, and will appear as a function of the angles which r makes with the n axes, and of the angles these axes make with one another. The poles of the n axes are defined to be the poles of the surface harmonics, and are also frequently spoken of as the poles of the solid harmonics Y_nr^n, Y_nr^{-n-1}. Any spherical harmonic is completely specified by means of its poles.

In order to express Y_n in terms of the positions of its poles, we apply the theorem (7) to the evaluation of V_n in (8). On putting

$$f_n(x,y,z)=\prod_{r=1}^{r=n}(l_rx+m_ry+n_rz),\ \text{we have}$$

$$Y_n=\frac{(2n!)}{2^nn!n!}\cdot\frac{1}{r^n}\left(1-\frac{r^2\nabla^2}{2.2n-1}+\frac{r^4\nabla^4}{2.4.2n-1.2n-3}\dots\right)\times\prod_{1}^{n}(l_rx+m_ry+n_rz).$$

By $\Sigma(\mu^s\lambda^{n-2s})$ we shall denote the sum of the products of s of the quantities μ, and $n-2s$ of the quantities λ; in any term each suffix is to occur once, and once only, every possible order being taken. We find

$$\Pi(lx+my+nz)=\Sigma(\lambda^n)r^n,\ \Delta^2\Pi(lx+my+nz)=2\Sigma(\mu^1\lambda^{n-2})r^{n-2},$$

and generally

$$\Delta^{2m}\Pi(lx+my+nz)=2^mm!\,\Sigma(\mu^m\lambda^{n-2m})r^{n-2m};$$

thus we obtain the following expression for Y_n, the surface harmonic which has given poles $h_1, h_2, \dots h_n$;

$$\begin{aligned}Y_n&=r^{n+1}\frac{(-1)^n}{n!}\frac{\partial^n}{\partial h_1\partial h_2\dots\partial h_n}\cdot\frac{1}{r}\\&=\underset{m=0}{S}\left\{(-1)^m\frac{(2n-2m)!}{2^{n-m}n!(n-m)!}\Sigma(\lambda^{n-2m}\mu^m)\right\}\end{aligned} \quad (9)$$

where S denotes a summation with respect to m from $m=0$ to $m=\frac{1}{2}n$, or $\frac{1}{2}(n-1)$, according as n is even or odd. This is Maxwell's general expression (*loc. cit.*) for a surface harmonic with given poles.

If the poles on a sphere of radius r are denoted by A, B, C…, we obtain from (9) the following expressions for the harmonics of the first four degrees:—

$$Y_1=\cos PA,\quad Y_2=\tfrac{1}{2}(3\cos PA\cos PB-\cos AB),$$

$$Y_3=\tfrac{1}{2}(15\cos PA\cos PB\cos PC-\cos PA\cos BC-\cos PB\cos CA-\cos PC\cos AB),$$

$$Y_4=\tfrac{1}{8}(35\cos PA\cos PB\cos PC\cos PD-5\Sigma\cos PA\cos PB\cos CD+\Sigma\cos AB\cos CD).$$

7. *Poles of Zonal, Tesseral and Sectorial Harmonics.*—Let the n axes of the harmonic coincide with the axis of z, we have then by (8) the harmonic

$$\frac{(-1)^nr^{n+1}}{n!}\frac{\partial^n}{\partial z^n}\frac{1}{r};$$

applying the theorem (7) to evaluate this expression, we have

$$\frac{(-1)^n r^{n+1}}{n!}\frac{\partial^n}{\partial z^n}\frac{1}{r}=\frac{(2n)!}{2^n n! n!}\frac{1}{r^n}\left\{1-\frac{r^2\nabla^2}{2\,.\,2n-1}+\frac{r^4\nabla^4}{2\,.\,4.2n-1\,.\,2n-3}-\right\}z^n$$
$$=\frac{(2n)!}{2^n n! n!}\left\{\mu^n-\frac{n(n-1)}{2.2n-1}\mu^{n-2}+\;.\;.\;.\right\},$$

the expression on the right side is $P^n(\mu)$, the zonal surface harmonic; we have therefore

$$P_n(\mu)=\frac{(-1)^n r^{n+1}}{n!}\frac{\partial^n}{\partial z^n}\frac{1}{r}.$$

The zonal harmonic has therefore all its poles coincident with the z axis. Next, suppose $n-m$ axes coincide with the z axis, and that the remaining m axes are distributed symmetrically in the plane of x, y at intervals π/m, the direction cosines of one of them being $\cos\alpha$ $\sin\alpha$, 0. We have

$$\prod_0^{m-1}\left\{\cos\left(\alpha+\frac{r\pi}{m}\right)\frac{\partial}{\partial x}+\sin\left(\alpha+\frac{r\pi}{m}\right)\frac{\partial}{\partial y}\right\}=\frac{1}{2^m}\Pi\left\{e^{\iota\left(\alpha+\frac{r\pi}{m}\right)}\left(\frac{\partial}{\partial x}-\iota\frac{\partial}{\partial y}\right)\right.$$
$$\left.+e^{-\iota\left(\alpha+\frac{r\pi}{m}\right)}\left(\frac{\partial}{\partial x}+\iota\frac{\partial}{\partial y}\right)\right\}.$$

Let $\xi=x+\iota y$, $\eta=x-\iota y$, the above product becomes

$$\prod_0^{m-1}\left\{e^{\iota\left(\alpha+\frac{r\pi}{m}\right)}\frac{\partial}{\partial\xi}+e^{-\iota\left(\alpha+\frac{r\pi}{m}\right)}\frac{\partial}{\partial\eta}\right\},$$

which is equal to

$$e^{(m-1)\frac{\iota\pi}{2}}\Pi\left\{e^{m\iota\alpha}\left(\frac{\partial}{\partial\xi}\right)^m-e^{-m\iota\alpha}\left(-\frac{\partial}{\partial\eta}\right)^m\right\};\text{ when }\alpha=0,\ \frac{\pi}{2m},$$

this becomes

$$e^{(m-1)\frac{\iota\pi}{2}}\left\{\left(\frac{\partial}{\partial\xi}\right)^m-(-1)^m\left(\frac{\partial}{\partial\eta}\right)^m\right\}\text{and}$$
$$e^{(m-1)\frac{\iota\pi}{2}}\left[\left(\frac{\partial}{\partial\xi}\right)^m+(-1)^m\left(\frac{\partial}{\partial\eta}\right)^m\right].$$

From (7), we find

$$\frac{\partial^{n-m}}{\partial z^{n-m}}\left(\frac{\partial}{\partial x}\pm\iota\frac{\partial}{\partial y}\right)^m\frac{1}{r}=\frac{(2n)!}{2^n n!}\frac{1}{r^{2n+1}}\left[1-\frac{r^2\Delta^2}{2.2n-1}+\ldots\right]z^{n-m}(x\pm\iota y)^m$$
$$=(-1)^n\frac{(2n)!}{2^n n!}\frac{1}{r^{n+1}}(\cos m\phi\pm\iota\sin m\phi)\sin^m\theta\left\{\cos^{n-m}\theta\right.$$
$$\left.-\frac{(n-m)(n-m-1)}{2.2n-1}\cos^{n-m-2}\theta+\ldots\right\},$$

hence

$$\frac{\partial^{n-m}}{\partial z^{n-m}}\left(\frac{\partial}{\partial x}\pm\iota\frac{\partial}{\partial y}\right)^m\frac{1}{r}=(-1)^n\frac{(n-m)!}{r^{n+1}}(\cos m\phi\pm\iota\sin m\phi)P_n^m(\cos\theta),$$

as we see on referring to (4); we thus obtain the formulae

$$\left.\begin{aligned}\frac{\partial^{n-m}}{\partial z^{n-m}}\left\{\left(\frac{\partial}{\partial\xi}\right)^m+\left(\frac{\partial}{\partial\eta}\right)^m\right\}\frac{1}{r}&=(-1)^n\frac{(n-m)!}{2^{m-1}r^{n+1}}\cos m\phi\,.\,P_n^m(\cos\theta)\\ \frac{\partial^{n-m}}{\partial z^{n-m}}\left\{\left(\frac{\partial}{\partial\xi}\right)^m-\left(\frac{\partial}{\partial\eta}\right)^m\right\}\frac{1}{r}&=(-1)^n\frac{(n-m)!}{2^{m-1}r^{n+1}}\sin m\phi\,.\,P_n^m(\cos\theta)\end{aligned}\right\}\quad(10)$$

It is thus seen that the tesseral harmonics of degree n and order m are those which have $n-m$ axes coincident with the z axis, and the other m axis distributed in the equatorial plane, at angular intervals π/m. The sectorial harmonics have all their axes in the equatorial plane.

8. *Determination of the Poles of a given Harmonic.*—It has been shown that a spherical harmonic $Y_n(x, y, z)$ can be generated by means of an operator

$$f_n\left(\frac{\partial}{\partial x},\frac{\partial}{\partial y},\frac{\partial}{\partial z}\right)\text{acting upon }\frac{1}{r},$$

the function f_n being so chosen that

$$Y_n(x,y,z)=(-1)^n\frac{(2n)!}{2^n n!}\left\{1-\frac{r^2\nabla^2}{2.2n-1}+\ldots\right\}f_n(x,y,z);$$

this relation shows that if an expression of the form

$$(x^2+y^2+{}^2)f_{n-2}(x,y,z)$$

is added to $f_n(x, y, z)$, the harmonic $Y_n(x, y, z)$ is unaltered; thus if Y_n be regarded as given, $f_n(x, y, z)=0$, is not uniquely determined, but has an indefinite number of values differing by multiples of $x^2+y^2+z^2$. In order to determine the poles of a given harmonic, f_n must be so chosen that it is resolvable into linear factors; it will be shown that this can be done in one, and only one, way, so that the poles are all real.

If x, y, z are such as to satisfy the two equations $Y_n(x, y, z)=0$, $x^2+y^2+z^2=0$, the equation $f_n(x, y, z)$ is also satisfied; the problem of determining the poles is therefore equivalent to the algebraical one of reducing Y_n to the product of linear factors by means of the relation $x^2+y^2+z^2=0$, between the variables. Suppose

$$Y_n(x,y,z)=A\prod_{s=1}^{m}(l_s x+m_s y+n_s z)+(x^2+y^2+z^2)V_{n-2}(x,y,z),$$

we see that the plane $l_s x+m_s y+n_s z=0$ passes through two of the $2n$ generating lines of the imaginary cone $x^2+y^2+z^2=0$, in which that cone is intersected by the cone $Y_n(x, y, z)=0$. Thus a pole (l_s, m_s, n_s) is the pole with respect to the cone $x^2+y^2+z^2=0$, of a plane passing through two of the generating lines; the number of systems of poles is therefore $n(2n-1)$, the number of ways of taking the $2n$ generating lines in pairs. Of these systems of poles, however, only one is real, viz. that in which the lines in each pair correspond to conjugate complex roots of the equations $Y_n=0$, $x^2+y^2+z^2=0$. Suppose

$$\frac{x}{\alpha_1+\iota\beta_1}=\frac{y}{\alpha_2+\iota\beta_2}=\frac{z}{\alpha_3+\iota\beta_3}$$

gives one generating line, then the conjugate one is given by

$$\frac{x}{\alpha_1-\iota\beta_1}=\frac{y}{\alpha_2-\iota\beta_2}=\frac{z}{\alpha_3-\iota\beta_3},$$

and the corresponding factor $lx+my+nz$ is

$$\begin{vmatrix}x & y & z\\ \alpha_1+\iota\beta_1 & \alpha_2+\iota\beta_2 & \alpha_3+\iota\beta_3\\ \alpha_1-\iota\beta_1 & \alpha_2-\iota\beta_2 & \alpha_3-\iota\beta_3\end{vmatrix},$$

which is real. It is obvious that if any non-conjugate pair of roots is taken, the corresponding factor, and therefore the pole, is imaginary. There is therefore only one system of real poles of a given harmonic, and its determination requires the solution of an equation of degree $2n$. This theorem is due to Sylvester (*Phil. Mag.* (1876), 5th series, vol. ii., " A Note on Spherical Harmonics ").

9. *Expression for the Zonal Harmonic with any Axis.*—The zonal surface harmonic, whose axis is in the direction

$$\frac{x'}{r'},\ \frac{y'}{r'},\ \frac{z'}{r'},\text{ is }P_n\left(\frac{xx'+yy'+zz'}{rr'}\right)$$

or $P_n(\cos\theta\cos\theta'+\sin\theta\sin\theta'\cos\phi-\phi')$; this is expressible as a linear function of the system of zonal, tesseral, and sectorial harmonics already found. It will be observed that it is symmetrical with respect to (x, y, z) and (x', y', z'), and must thus be capable of being expressed in the form

$$a_0P_n(\cos\theta)P_n(\cos\theta')+\sum_1^n a_m P_n^m(\cos\theta)P_n^m(\cos\theta')\cos m(\phi-\phi'),$$

and it only remains to determine the co-efficients a_0, a_1, ...a_m...a_n. To find this expression, we transform $(x'x+y'y+z'z)^n$, where x, y, z satisfy the condition $x^2+y^2+z^2=0$; writing $\xi=x+\iota y$, $\eta=x-\iota y$, $\xi'=x'+\iota y'$, $\eta'=x'-\iota y'$, we have

$$(xx'+yy'+zz')^n=(\tfrac{1}{2}\eta'\xi+\tfrac{1}{2}\xi'\eta+zz')^n$$

which equals

$$(zz')^n+\Sigma\Sigma\frac{n!}{a!b!(n-a-b)!}\left\{\frac{\eta'^a\xi'^b\xi^a\eta^b+\eta'^b\xi'^a\xi^b\eta^a}{2^{a+b}}\right\}(zz')^{n-a-b},$$

the summation being taken for all values of a and b, such that $a+b\leqq n$, $a>b$; the values $a=0$, $b=0$ corresponding to the term $(zz')^n$. Using the relation $\xi\eta=-z^2$, this becomes

$$(xx'+yy'+zz')^n=(zz')^n+\Sigma\Sigma\frac{(-1)^b}{2^{a+b}}\frac{n!}{a!b!(n-a-b)!}(\xi'\eta')^b z'^{n-a-b}$$
$$\{(\eta'\xi)^{a-b}+(\xi'\eta)^{a-b}\}z^{n-a+b},$$

putting $a-b=m$, the coefficient of $\xi^m z^{n-m}$, on the right side is

$$\sum\frac{(-1)^b}{2^{m+2b}}\frac{n!}{b!(m+b)!(n-m-2b)!}(\xi'\eta')^b\eta'^m z'^{n-m-2b},$$

from $b=0$ to $b=\frac{1}{2}(n-m)$, or $\frac{1}{2}(n-m-1)$, according as $n-m$ is even or odd. This coefficient is equal to

$$\frac{n!}{2^m m!(n-m)!}(x'-\iota y')^m\left\{z'^{n-m}-\frac{(n-m)(n-m-1)}{2.2m+2}z'^{n-m-2}(x'^2+y'^2)\right.$$
$$\left.+\frac{(n-m)(n-m-1)(n-m-2)(n-m-3)}{2.4.2m+2.2m+3}z'^{n-m-4}(x'^2+y'^2)^2-\right\};$$

in order to evaluate this coefficient, put $z=1$, $x'=\iota\cos\alpha$, $y'=\iota\sin\alpha$, then this coefficient is that of $(\iota\cos\alpha+\sin\alpha)^m$, or of $\iota^m e^{-m\iota\alpha}$ in the expansion of $(z'+\iota x'\cos\alpha+\iota y'\sin\alpha)^n$ in powers of $e^{-\iota\alpha}$ and $e^{\iota\alpha}$, this has been already found, thus the coefficient is

$$\frac{n!}{(n+m)!}e^{-\iota m\phi'}P_n^m(\cos\theta').r'^n.$$

Similarly the coefficient of $\eta^m z^{n-m}$ is

$$\frac{n!}{(n+m)!}e^{+\iota m\phi'}P_n^m(\cos\theta')r'^n;$$

hence we have

$$\frac{1}{r'^n}(xx'+yy'+zz')^n=z^nP_n(\cos\theta')+n!\sum_1^n P_n^m(\cos\theta')\{\cos m\phi'(\xi^m+\eta^m)$$
$$+\iota\sin m\phi'(\eta^m-\xi^m)\}\frac{z^{n-m}}{(n+m)!}.$$

In this result, change x, y, z into

$$\frac{\partial}{\partial x},\ \frac{\partial}{\partial y},\ \frac{\partial}{\partial z},$$

and let each side operate on $1/r$, then in virtue of (10), we have

$$(rr')^n P_n\left(\frac{xx'+yy'+zz'}{rr'}\right) = P_n(\cos\theta\cos\theta'+\sin\theta\sin\theta'\cos\overline{\phi-\phi'})$$
$$= P_n(\cos\theta)P_n(\cos\theta') + 2\Sigma\frac{(n-m)!}{(n+m)!}P_n^m(\cos\theta)P_n^m(\cos\theta')\cos m(\phi-\phi') \quad (11)$$

which is known as the addition theorem for the function P_n.

It has incidentally been proved that

$$P_n^m(\cos\theta) = \frac{(n+m)!}{2^m(n-m)!}\sin^m\theta\left\{\cos^{n-m}\theta - \frac{(n-m)(n-m-1)}{2.2m+2}\cos^{n-m-2}\theta\sin^2\theta + \right\}, \quad (12)$$

which is an expression for P_n^m (cos θ) alternative to (4).

10. *Legendre's Coefficients.*—The reciprocal of the distance of a point (r, θ, ϕ) from a point on the z axis distant r' from the origin is

$$(r^2-2rr'\mu+r'^2)^{-\frac{1}{2}}$$

which satisfies Laplace's equation, μ denoting cos θ. Writing this expression in the forms

$$\frac{1}{r'}\left\{1-2\frac{r}{r'}\mu+\frac{r^2}{r'^2}\right\}^{-\frac{1}{2}},\ \frac{1}{r}\left\{1-2\frac{r'}{r}\mu+\frac{r'^2}{r^2}\right\}^{-\frac{1}{2}},$$

it is seen that when $r < r'$, the expression can be expanded in a convergent series of powers of r/r', and when $r' < r$ in a convergent series of powers of r'/r. We have, when $h^2(2\mu-h)^2<1$

$$(1-2h\mu+h^2)^{-\frac{1}{2}} = 1+h(2\mu-h)+\frac{1.3}{2.4}h^2(2\mu-h)^2+\dots$$
$$+\frac{1.3.5\dots2n-1}{2.4\dots2n}h^n(2\mu-h)^n+\dots$$

and since the series is absolutely convergent, it may be rearranged as a series of powers of h, the coefficient of h^n is then found to be

$$\frac{1.3.5\dots2n-1}{1.2.3\dots n}\left\{\mu^n-\frac{n(n-1)}{2.2n-1}\mu^{n-2}+\frac{n(n-1)(n-2)(n-3)}{2.4.2n-1.2n-3}\mu^{n-4}\dots\right\}$$

this is the expression we have already denoted by $P_n(\mu)$; thus

$$(1-2h\mu+h^2)^{-\frac{1}{2}} = P_0(\mu)+hP_1(\mu)+\dots+h^nP_n(\mu)+\dots, \quad (13)$$

the function $P_n(\mu)$ may thus be defined as the coefficient of h^n in this expansion, and from this point of view is called the Legendre's coefficient or Legendre's function of degree n, and is identical with the zonal harmonic. It may be shown that the expansion is valid for all real and complex values of h and μ, such that mod. h is less than the smaller of the two numbers mod. $(\mu\pm\sqrt{\mu^2-1})$. We now see that

$$(r^2-2rr'\mu+r'^2)^{-\frac{1}{2}}$$

is expressible in the form

$$\sum_0^\infty \frac{r^n}{r'^{n+1}}P_n(\mu)$$

when $r < r'$, or

$$\sum_0^\infty \frac{r'^n}{r^{n+1}}P_n(\mu)$$

when $r' < r$; it follows that the two expressions $r^nP_n(\mu)$, $r^{-n-1}P_n(\mu)$ are solutions of Laplace's equation.

The values of the first few Legendre's coefficients are

$$P_0(\mu)=1,\ P_1(\mu)=\mu,\ P_2(\mu)=\frac{1}{2}(3\mu^2-1),\ P_3(\mu)=\frac{1}{2}(5\mu^3-3\mu)$$
$$P_4(\mu)=\frac{1}{8}(35\mu^4-30\mu^2+3),\ P_5(\mu)=\frac{1}{8}(63\mu^5-70\mu^3+15\mu)$$
$$P_6(\mu)=\frac{1}{16}(231\mu^6-315\mu^4+105\mu^2-5),\ P_7(\mu)=\frac{1}{16}(429\mu^7-693\mu^5+315\mu^3-35\mu).$$

We find also

$$P_n(1)=1,\ P_n(-1)=(-1)^n$$
$$P_n(0)=0, \text{ or } (-1)^{\frac{1}{2}n}\frac{1.3.5\dots n-1}{2.4\dots n}$$

according as n is odd or even; these values may be at once obtained from the expansion (13), by putting $\mu=1,\ 0,-1$.

11. *Additional Expressions for Legendre's Coefficients.*—The expression (3) for $P_n(\mu)$ may be written in the form

$$P_n(\mu)=\frac{(2n)!}{2^nn!n!}\mu^nF\left(-\frac{n}{2},\frac{1-n}{2},\frac{1}{2}-n,\frac{1}{\mu^2}\right)$$

with the usual notation for hypergeometric series.

On writing this series in the reverse order

$$P_n(\mu)=(-1)^{\frac{1}{2}n}\frac{n!}{2^n\left(\frac{1}{2}n\right)!\left(\frac{1}{2}n\right)!}F\left(-\frac{n}{2},\frac{n+1}{2},\frac{1}{2},\mu^2\right)$$

or

$$(-1)^{\frac{n-1}{2}}\frac{n!}{2^{n-1}\frac{n-1}{2}!\frac{n-1}{2}!}\mu F\left(-\frac{n-1}{2},\frac{n}{2}+1,\frac{3}{2},\mu^2\right)$$

according as n is even or odd.

From the identity

$$(1-2h\cos\theta+h^2)^{-\frac{1}{2}}=(1-he^{\iota\theta})^{-\frac{1}{2}}(1-he^{-\iota\theta})^{-\frac{1}{2}},$$

it can be shown that

$$P_n(\cos\theta)=\frac{1.3.5\dots2n-1}{2.4.6\dots2n}\left\{\cos n\theta+\frac{1.n}{1.2n-1}\cos(n-2)\theta+\frac{1.3.n(n-1)}{1.2.(2n-1)(2n-3)}\cos(n-4)\theta+\right\}. \quad (14)$$

By (13), or by the formula

$$P_n(\mu)=\frac{1}{2^nn!}\frac{d^n}{d\mu^n}(\mu^2-1)^n$$

which is known as Rodrigue's formula, we may prove that

$$P^n(\cos\theta)=1-\frac{(n+1)n}{1^2}\sin^2\frac{\theta}{2}+\frac{(n+2)(n+1)n(n-1)}{1^2.2^2}\sin^4\frac{\theta}{2}\dots$$
$$=F\left(n+1,-n,1,\sin^2\frac{\theta}{2}\right). \quad (15)$$

Also that

$$P_n(\cos\theta)=\cos^{2n}\frac{\theta}{2}\left\{1-\frac{n^2}{1^2}\tan^2\frac{\theta}{2}+\frac{n^2(n-1)^2}{1^2.2^2}\tan^4\frac{\theta}{2}-\dots\right\}$$
$$=\cos^{2n}\frac{\theta}{2}F\left(-n,-n,1,-\tan^2\frac{\theta}{2}\right). \quad (16)$$

By means of the identity

$$(1-2h\mu+h^2)^{-\frac{1}{2}}=(1-h\mu)^{-1}\left\{1+\frac{h^2(1-\mu^2)}{(1-h\mu)^2}\right\}^{-\frac{1}{2}},$$

it may be shown that

$$P_n(\cos\theta)=\cos^n\theta\left\{1-\frac{n(n-1)}{2^2}\tan^2\theta+\frac{n(n-1)(n-2)(n-3)}{2^2.4^2}\tan^4\theta-\dots\right\}$$
$$=\cos^n\theta F(-\tfrac{1}{2}n,\tfrac{1}{2}-\tfrac{1}{2}n,1,-\tan^2\theta). \quad (17)$$

Laplace's definite integral expression (6) may be transformed into the expression

$$\frac{1}{\pi}\int_0^\pi\frac{d\phi}{(\mu-\sqrt{\mu^2-1}\cos\psi)^{n+1}},$$

by means of the relation

$$(\mu+\sqrt{\mu^2-1}\cos\phi)(\mu-\sqrt{\mu^2-1}\cos\psi)=1.$$

Two definite integral expressions for $P_n(\mu)$ given by Dirichlet have been put by Mehler into the forms

$$P_n(\cos\theta)=\frac{2}{\pi}\int_0^\theta\frac{\cos(n+\frac{1}{2})\phi}{\sqrt{2\cos\phi-2\cos\theta}}d\phi=\frac{2}{\pi}\int_\theta^\pi\frac{\sin(n+\frac{1}{2})\phi}{\sqrt{2\cos\theta-2\cos\phi}}d\phi.$$

When n is large, and θ is not nearly equal to 0 or to π, an approximate value of $P_n(\cos\theta)$ is $\{2/n\pi\sin\theta\}^{\frac{1}{2}}\sin\{(n+\frac{1}{2})\theta+\frac{1}{4}\pi\}$.

12. *Relations between successive Legendre's Coefficients and their Derivatives.*—If $(1-2h\mu+h^2)^{-\frac{1}{2}}$ be denoted by u, we find

$$(1-2h\mu+h^2)\frac{\partial u}{\partial h}+(h-\mu)u=0;$$

on substituting Σh^nP_n for u, and equating to zero the coefficient of h^n, we obtain the relation

$$nP_n-(2n-1)\mu P_{n-1}+(n-1)P_{n-2}=0.$$

From Laplace's definite integral, or otherwise, we find

$$(\mu^2-1)\frac{dP_n}{d\mu}=n(\mu P_n-P_{n-1})=-(n+1)(\mu P^n-P^{n+1}).$$

We may also show that

$$\mu\frac{dP_n}{d\mu}-\frac{dP_{n-1}}{d\mu}=nP_n$$
$$(n+1)P_n=-\mu\frac{dP_n}{d\mu}+\frac{dP_{n+1}}{d\mu}$$
$$(2n+1)P_n=\frac{dP_{n+1}}{d\mu}-\frac{dP_{n-1}}{d\mu}$$
$$(2n+1)\mu\frac{dP_n}{d\mu}=(n+1)\frac{dP_{n-1}}{d\mu}+n\frac{dP_{n+1}}{d\mu}$$
$$(2n+1)(\mu^2-1)\frac{dP_n}{d\mu}=n(n+1)(P_{n+1}-P_{n-1})$$
$$\frac{dP_n}{d\mu}=(2n-1)P_{n-1}+(2n-5)P_{n-3}+(2n-9)P_{n-5}+\dots$$

the last term being $3P_1$ or P_0 according as n is even or odd.

13. *Integral Properties of Legendre's Coefficients.*—It may be shown that if $P_n(\mu)$ be multiplied by any one of the numbers $1,\mu,\mu^2,\dots\mu^{n-1}$ and the product be integrated between the limits $1,-1$ with respect to μ, the result is zero, thus

$$\int_{-1}^1\mu^kP_n(\mu)d\mu=0,\ \alpha=0,1,2,\dots n-1. \quad (18)$$

To prove this theorem we have

$$\int_{-1}^1\mu^kP_n(\mu)d\mu=\frac{1}{2^nn!}\int_{-1}^1\mu^k\frac{d^n}{d\mu^n}(\mu^2-1)^nd\mu,$$

on integrating the expression k times by parts, and remembering that $(\mu^2-1)^n$ and its first $n-1$ derivatives all vanish when $\mu=\pm 1$, the theorem is established. This theorem derives additional importance from the fact that it may be shown that $AP_n(\mu)$ is the only rational integral function of degree n which has this property; from this arises the importance of the functions P_n in the theory of quadratures.

The theorem which lies at the root of the applicability of the functions P_n to potential problems is that if n and n' are unequal integers

$$\int_{-1}^{1} P_{n'}(\mu)P_n(\mu)d\mu=0, \tag{19}$$

which may be stated by saying that the integral of the product of two Legendre's coefficients of different degree taken over the whole of a spherical surface with its centre at the origin is zero; this is the fundamental harmonic property of the functions. It is immediately deducible from (18), for if $n'<n$, $P_{n'}(\mu)$ is a linear function of powers of μ, whose indices are all less than n.

When $n'=n$, the integral in (19) becomes $\int_{-1}^{1}\{P_n(\mu)\}^2d\mu$; to evaluate this we write it in the form

$$\frac{1}{2^{2n}n!n!}\int_{-1}^{1}\frac{d^n}{d\mu^n}(\mu^2-1)^n\frac{d^n}{d\mu^n}(\mu^2-1)^n d\mu;$$

on integrating n times by parts, this becomes

$$\frac{(-1)^n}{2^{2n}n!n!}\int_{-1}^{1}(\mu^2-1)^n\frac{d^{2n}}{d\mu^{2n}}(\mu^2-1)^n d\mu, \text{ or } \frac{(2n)!}{2^{2n}n!n!}\int_{-1}^{1}(1-\mu^2)^n\mu,$$

which on putting

$$u=\frac{1}{2}(1-\mu, \text{ becomes } 2\frac{(2n)!}{n!\ n!}\int_{-1}^{1}u^n(1-u)^n du,$$

hence

$$\int_{-1}^{1}\{P_n(\mu)\}^2d\mu=\frac{2}{2n+1}. \tag{20}$$

14. *Expansion of Functions in Series of Legendre's Coefficients.*—If it be assumed that a function $f(\mu)$ given arbitrarily in the interval $\mu=-1$ to $+1$, can be represented by a series of Legendre's coefficients $a_0+a_1P_1(\mu)+a_2P_2(\mu)+\ldots+a_nP_n(\mu)+\ldots$ and it be assumed that the series converges in general uniformly within the interval, the coefficient a can be determined by using (19) and (20); we see that the theorem (19) plays the same part as the property $\int_0^{\pi}{\sin \atop \cos} n\theta {\sin \atop \cos} n'\theta d\theta=0$, $(n\neq n')$ does in the theory of the expansion of functions in series of circular functions. On multiplying the series by $P_n(\mu)$, we have

$$a_n\int_{-1}^{1}\{P_n(\mu)\}^2d\mu=\int_{-1}^{1}f(\mu)P_n(\mu)d\mu$$

hence

$$a_n=\frac{2n+1}{2}\int_{-1}^{1}f(\mu)P^n(\mu)d\mu,$$

hence the series by which $f(\mu)$ is in general represented in the interval is

$$\sum\frac{2n+1}{2}P_n(\mu)\int_{-1}^{1}f(\mu')P_n(\mu')d\mu'. \tag{21}$$

The proof of the possibility of this representation, including the investigation of sufficient conditions as to the nature of the function $f(\mu)$, that the series may in general converge to the value of the function requires an investigation, for which we have not space, similar in character to the corresponding investigations for series of circular functions (see FOURIER'S SERIES). A complete investigation of this matter is given by Hobson, *Proc. Lond. Math. Soc.*, 2nd series, vol. 6, p. 388, and vol. 7, p. 24. See also Dini's *Serie di Fourier*.

The expansion may be applied to the determination at an external and an internal point of the potential due to a distribution of matter of surface density $f(\mu)$ placed on a spherical surface $r=a$. If

$$V_i=\Sigma A_n'\frac{r^n}{a^{n+1}}P_n(\mu),\ V_0=\Sigma A_n\frac{a^n}{r^{n+1}}P_n(\mu),$$

we see that V_i, V_0 have the characteristic properties of potential functions for the spaces internal to, and external to, the spherical surface respectively; moreover, the condition that V_i is continuous with V_0 at the surface $r=a$, is satisfied. The density of a surface distribution which produces these potentials is in accordance with a known theorem in the potential theory, given by

$$\sigma=\frac{1}{4\pi}\left(\frac{\partial V_i}{\partial r}-\frac{\partial V_0}{\partial r}\right)r=a,$$

hence

$\sigma=\frac{1}{4\pi a^2}\Sigma(2n+1)A_nP_n(\mu)$; on comparing this with the series (21), we have $A_n=2\pi a^2\int_{-1}^{1}f(\mu')P_n(\mu')d\mu'$,

hence

$$\begin{cases}V_i=2\pi a\Sigma\frac{r^n}{a^n}P_n(\mu)\int_{-1}^{1}f(\mu')P_n(\mu')d\mu'\\ V_0=2\pi a\Sigma\frac{a^{n+1}}{r^{n+1}}P_n(\mu)\int_{-1}^{1}f(\mu')P_n(\mu')d\mu'\end{cases}$$

are the required expressions for the internal and external potentials due to the distribution of surface density $f(\mu)$.

15. *Integral Properties of Spherical Harmonics.*—The fundamental harmonic property of spherical harmonics, of which property (19) is a particular case, is that if $Y_n(x, y, z)$, $Z_{n'}(x, y, z)$ be two (ordinary) spherical harmonics, then,

$$\iint Y_n(x, y, z)Z_{n'}(x, y, x)dS=0, \tag{22}$$

when n and n' are unequal, the integration being taken for every element dS of a spherical surface, of which the origin is the centre.

Since $\nabla^2Y_n=0$, $\nabla^2Z_{n'}=0$, we have

$$\iiint(Y_n\nabla^2Z_{n'}-Z_{n'}\nabla^2Y_{n'})dxdydz=0,$$

the integration being taken through the volume of the sphere of radius r; this volume integral may be written

$$\iiint\left\{\frac{\partial}{\partial x}\left(Y_n\frac{\partial Z_{n'}}{\partial x}-Z_{n'}\frac{\partial Y_n}{\partial x}\right)+\frac{\partial}{\partial y}\left(Y_n\frac{\partial Z_{n'}}{\partial y}-Z_{n'}\frac{\partial Y_n}{\partial y}\right)+\frac{\partial}{\partial z}\left(Y_n\frac{\partial Z_{n'}}{\partial z}-Z_{n'}\frac{\partial Y_n}{\partial z}\right)\right\}dxdydz=0;$$

by a well-known theorem in the integral calculus, the volume integral may be replaced by a surface integral over the spherical surface; we thus obtain

$$\iint\left\{\frac{x}{r}\left(Y_n\frac{\partial Z_{n'}}{x}-Z_{n'}\frac{\partial Y_n}{\partial x}\right)+\frac{y}{r}\left(Y_n\frac{\partial Z_{n'}}{\partial y}-Z_{n'}\frac{\partial Y_n}{\partial y}\right)+\frac{z}{r}\left(Y_n\frac{\partial Z_{n'}}{\partial z}-Z_{n'}\frac{\partial Y_n}{\partial y}\right)\right\}dS=0;$$

on using Euler's theorem for homogeneous functions, this becomes

$$\frac{n'-n}{r}\iint Y_nZ_{n'}dS=0,$$

whence the theorem (22), which is due to Laplace, is proved.

The integral over a spherical surface of the product of a spherical harmonic of degree n, and a zonal surface harmonic P_n of the same degree, the pole of which is at (x', y', z') is given by

$$\iint Y_n(x, y, z)P_n dS=\frac{4\pi}{2n+1}a^{n+2}Y_n(x', y', z'); \tag{23}$$

thus the value of the integral depends on the value of the spherical harmonic at the pole of the zonal harmonic.

This theorem may also be written

$$\int_0^{2\pi}\int_{-1}^{1}V_n(\theta, \phi)P_n(\cos\theta\cos\theta'+\sin\theta\sin\theta'\cos\overline{\phi-\phi'})d\mu d\phi=\frac{4\pi}{2n+1}V_n(\theta', \phi').$$

To prove the theorem, we observe that V_n is of the form

$$a_0P_n(\mu)+\sum_1^n(a_m\cos m\phi+b_m\sin m\phi)P_n^m(\mu);$$

to determine a_0 we observe that when $\mu=1$,

$$P_n(\mu)=1,\ P_n^m(\mu)=0;$$

hence a_0 is equal to the value $V_n(0)$ of $V_n\ (\theta, \phi)$ at the pole $\theta=0$ of $P_n(\mu)$. Multiply by $P_n(\mu)$ and integrate over the surface of the sphere of radius unity, we then have

$$\int_0^{2\pi}\int_{-1}^{1}V_n(\theta, \phi)P_n(\mu)d\mu d\phi=a_0\int_0^{2\pi}\int_{-1}^{1}\{P_n(\mu)\}^2d\mu d\phi=\frac{4\pi}{2n+1}a_0=\frac{4\pi}{2n+1}V_n(0),$$

if instead of taking $\mu=1$ as the pole of $P_n(\mu)$ we take any other point (μ', ϕ') we obtain the theorem (23).

If $f(x, y, z)$ is a function which is finite and continuous throughout the interior of a sphere of radius R, it may be shown that

$$\iint Y_n(x, y, z)f(x, y, z)dS=4\pi R^{2n+2}\frac{2^nn!}{(2n+1)!}\left\{1+\frac{R^2\nabla^2}{2.2n+3}+\frac{R^4\nabla^4}{2.4.2n+3.2n+5}+\ldots\right\}Y_n\left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z}\right)f(x, y, z)$$

where x, y, z are put equal to zero after the operations have been performed, the integral being taken over the surface of the sphere of radius R (see Hobson, "On the Evaluation of a certain Surface Integral," *Proc. Lond. Math. Soc.* vol. xxv.).

The following case of this theorem should be remarked: If $f_n(x, y, z)$ is homogeneous and of degree n

$$\iint Y_n(x, y, z)f_n(x, y, z)dS=4\pi R^{2n+2}\frac{2^nn!}{(2n+1)!}Y_n\left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z}\right)f_n(x, y, z)$$

if $f_n(x, y, z)$ is a spherical harmonic, we obtain from this a theorem, due to Maxwell (*Electricity*, vol. i. ch. ix.),

$$\iint Y_n(x, y, z)f_n(x, y, z)dS=\frac{4\pi R^{2n+2}}{2n+1}\frac{1}{n!}\frac{\partial^n}{\partial h_1\partial h_2\ldots\partial h}f_n(x, y, z)$$

where $h_1h_2\ldots h_n$ are the axes of Y_n. Two harmonics of the same degree are said to be conjugate, when the surface integral of their product vanishes; if Y_n, Z_n are two such harmonics, the addition of conjugacy is

$$Y_n\left(\frac{\partial}{\partial x}, \frac{\partial'}{\partial y}, \frac{\partial}{\partial z}\right)Z_n(x, y, z) = 0.$$

Lord Kelvin has shown how to express the conditions that $2n+1$ harmonics of degree n form a conjugate system (see *B. A. Report*, 1871).

16. *Expansion of a Function in a Series of Spherical Harmonics.*—It can be shown that under certain restrictions as to the nature of a function $F(\mu, \phi)$ given arbitrarily over the surface of a sphere, the function can be represented by a series of spherical harmonics which converges in general uniformly. On this assumption we see that the terms of the series can be found by the use of the theorems (22), (23). Let $F(\mu, \phi)$ be represented by

$$V_0(\mu, \phi) + V_1(\mu, \phi) + \ldots + V_n(\mu, \phi) + \ldots;$$

change μ, ϕ into μ', ϕ' and multiply by

$$P_n(\cos\theta\cos\theta' + \sin\theta\sin\theta'\cos\overline{\phi-\phi'}),$$

we have then

$$\int_0^{2\pi}\int_{-1}^{1}F(\mu', \phi')P_n(\cos\theta\cos\theta' + \sin\theta\sin\theta'\cos\overline{\phi-\phi'})d\mu'd\phi'$$
$$= \int_0^{2\pi}\int_0^{1}V_n(\mu', \phi')P_n(\cos\theta\cos\theta' + \sin\theta\sin\theta'\cos\overline{\phi-\phi'})d\mu'd\phi'$$
$$= \frac{4\pi}{2n+1}V_n(\theta, \phi),$$

hence the series which represents $F(\mu, \phi)$ is

$$\tfrac{1}{4}\pi\sum_0^\infty(2n+1)\int_0^{2\pi}\int_{-1}^{1}F(\mu', \phi')P_n(\cos\theta\cos\theta'$$
$$+\sin\theta\sin\theta'\cos\overline{\phi-\phi'})d\mu'd\phi'. \qquad (24)$$

A rational integral function of $\sin\theta\cos\phi$, $\sin\theta\sin\phi$, $\cos\theta$ of degree n may be expressed as the sum of a series of spherical harmonics, by assuming

$$f_n(x, y, z) = Y_n + r^2Y_{n-2} + r^4Y_{n-4} + \ldots$$

and determining the solid harmonics Y_n, $Y_{n-2}, \ldots$ and then letting $r = 1$, in the result.

Since $\nabla^2(r^{2s}Y_{n-2s}) = 2s(2n-2s+1)r^{2s-2}Y_{n-2s}$, we have

$$\nabla^2 f_n = 2(2n-1)Y_{n-2} + 4(2n-3)r^2Y_{n-4} + 6(2n-5)r^4Y_{n-6} + \ldots$$
$$\nabla^4 f_n = 2.4(2n-3)(2n-5)Y_{n-4} + 4.6(2n-5)(2n-7)r^2Y_{n-6} + \ldots$$

the last equation being

$$\nabla^n f_n = n(n+1)(n-2)(n-1)\ldots Y_0, \text{ if } n \text{ is even,}$$

or

$$\nabla^{n-1}f_n = (n-1)(n+2)(n-3)n\ldots Y_1, \text{ if } n \text{ is odd}$$

from the last equation Y_0 or Y_1 is determined, then from the preceding one Y_2 or Y_3, and so on. This method is due to Gauss (see *Collected Works*, v. 630).

As an example of the use of spherical harmonics in the potential theory, suppose it required to calculate at an external point, the potential of a nearly spherical body bounded by $r = a(1+\epsilon u)$, the body being made of homogeneous material of density unity, and u being a given function of θ, ϕ, the quantity ϵ being so small that its square may be neglected. The potential is given by

$$\int_0^{2\pi}\int_{-1}^{1}\int_0^{a(1+\epsilon u')}\{r^2 + r'^2 - 2rr'\cos\gamma\}^{-\frac{1}{2}}dr'd\mu'd\phi'.$$

where γ is the angle between r and r'; now let u' be expanded in a series

$$Y_0(\mu', \phi') + Y_1(\mu', \phi') + \ldots + Y_n(\mu', \phi') + \ldots$$

of surface harmonics; we may write the expression for the potential

$$\int_0^{2\pi}\int_{-1}^{1}\int_0^{a(1+\epsilon u')}\left\{\frac{1}{r} + \frac{r'}{r^2}P_1(\cos\gamma) + \ldots\right.$$
$$\left. + \frac{r'^n}{r^{n+1}}P_n(\cos\gamma) + \ldots\right\}r'^2dr'd\mu'd\phi'$$

which is,

$$\int_0^{2\pi}\int_{-1}^{1}\left\{\frac{a^3}{3r}(1+3\epsilon u') + \frac{1}{4}\frac{a^4}{r^2}(1+4\epsilon u')P_1 + \ldots\right.$$
$$\left. + \frac{1}{n+3}\frac{a^{n-3}}{r^{n+1}}(1+\overline{n+3}\epsilon u')P_n(\cos\gamma)\right\}d\mu'd\phi'$$

on substituting for u' the series of harmonics, and using (22), (23), this becomes

$$4\pi a^2\left[\frac{1}{3}\frac{a}{r} + \epsilon\left\{\frac{a^3}{3r^2}Y_1(\mu, \phi) + \frac{a^3}{5r^3}Y_2(\mu, \phi) + \ldots\right.\right.$$
$$\left.\left. + \frac{a^{n+1}}{(2n+1)r^{n-1}}Y_n(\mu, \phi) + \ldots\right\}\right]$$

which is the required potential at the external point (r, θ, ϕ).

17. *The Normal Solutions of Laplace's Equation in Polars.*—If h_1, h_2, h_3 be the parameters of three orthogonal sets of surfaces, the length of an elementary arc ds may be expressed by an equation of the form $ds^2 = \frac{1}{H_1^2}dh_1^2 + \frac{1}{H_2^2}dh_2^2 + \frac{1}{H_3^2}dh_3^2$, where H_1, H_2, H_3 are functions of h_1, h_2, h_3, which depend on the form of these parameters; it is known that Laplace's equation when expressed with h_1, h_2, h as independent variables, takes the form

$$\frac{\partial}{\partial h_1}\left(\frac{H_1}{H_2H_3}\frac{\partial V}{\partial h_1}\right) + \frac{\partial}{\partial h_2}\left(\frac{H_2}{H_3H_1}\frac{\partial V}{\partial h_2}\right) + \frac{\partial}{\partial h_3}\left(\frac{H_3}{H_1H_2}\frac{\partial V}{\partial h_3}\right) = 0. \quad (25)$$

In case the orthogonal surfaces are concentric spheres, co-axial circular cones, and planes through the axes of the cones, the parameters are the usual polar co-ordinates r, θ, ϕ, and in this case $H_1 = 1$, $H_2 = \frac{1}{r}$, $H_3 = \frac{1}{r\sin\theta'}$, thus Laplace's equation becomes

$$\frac{\partial}{\partial r}\left(r^2\frac{\partial V}{\partial r}\right) + \frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial V}{\partial\theta}\right) + \frac{1}{\sin^2\theta}\frac{\partial^2 V}{\partial\phi^2} = 0.$$

Assume that $V = R\Theta\Phi$ is a solution, R being a function of r only, Θ of θ only, Φ of ϕ only; we then have

$$\frac{1}{R}\frac{d}{dr}\left(r^2\frac{dR}{dr}\right) + \frac{1}{\Theta\sin\theta}\frac{d}{d\theta}\left(\sin\theta\frac{d\Theta}{d\theta}\right) + \frac{1}{\sin^2\theta.\Phi}\frac{d^2\Phi}{d\phi^2} = 0.$$

This can only be satisfied if $\frac{1}{R}\frac{d}{dr}\left(r^2\frac{dR}{dr}\right)$ is a constant, say $n(n+1)$, $\frac{1}{\Phi}\frac{d^2\Phi}{d\phi^2}$ is a constant, say $-m^2$, and Θ satisfies the equation

$$\frac{1}{\sin\theta}\frac{d}{d\theta}\left(\sin\theta\frac{d\Theta}{d\theta}\right) + \left\{n(n+1) - \frac{m^2}{\sin^2\theta}\right\}\Theta = 0,$$

if we write u for Θ, and μ for $\sin\theta$, this equation becomes

$$\frac{d}{d\mu}\left\{(1-\mu^2)\frac{du}{d\mu}\right\} + \left\{n(n+1) - \frac{m^2}{1-\mu^2}\right\}u = 0. \quad . \quad (26)$$

From the equations which determine R, Θ, u, it appears that Laplace's equation is satisfied by

$$\begin{matrix} r^n \\ r^{-n-1}\end{matrix}\begin{matrix}\cos \\ \sin\end{matrix}m\phi\,.\,u_n^m$$

where u is any solution of (26); this product we may speak of as the normal solution of Laplace's equation in polar co-ordinates; it will be observed that the constants n, m may have any real or complex values.

18. *Legendre's Equation.*—If in the above normal solution we consider the case $m = 0$, we see that

$$\begin{matrix} r^n \\ r^{-n-1}\end{matrix}u_n$$

is the normal form, where u_n satisfies the equation

$$\frac{d}{d\mu}\left\{(1-\mu^2)\frac{du}{d\mu}\right\} + n(n+1)u = 0, \quad . \quad . \quad (27)$$

known as Legendre's equation; we shall here consider the special case in which n is a positive integer. One solution of (27) will be the Legendre's coefficient $P_n(\mu)$, and to find the complete primitive we must find another particular integral; in considering the forms of solution, we shall consider μ to be not necessarily real and between ± 1. If we assume

$$u = \mu^m + a_2\mu^{m-2} + a_4\mu^{m-4} + \ldots$$

as a solution, and substitute in the equation (27), we find that $m = n$, or $-n-1$, and thus we have as solutions, on determining the ratios of the coefficients in the two cases,

$$\alpha\left\{\mu^n - \frac{n(n-1)}{2\,.\,2n-1}\mu^{n+2} + \ldots\right\}$$

and

$$\beta\left\{\frac{1}{\mu^{n+1}} + \frac{(n+1)(n+2)}{2\,.\,2n+3}\frac{1}{\mu^{n+3}} + \frac{(n+1)(n+2)(n+3)(n+4)}{2\,.\,4\,.\,2n+3\,.\,2n+5}\frac{1}{\mu^{n+5}} + \ldots\right\}$$

the first of these series is (n integral) finite, and represents $P_n(\mu)$, the second is an infinite series which is convergent when mod $\mu > 1$. If we choose the constant β to be $\frac{1\,.\,2\,.\,3\,.\,.\,.\,n}{3\,.\,5\,.\,.\,.\,2n+1}$, the second solution may be denoted by $Q_n(\mu)$, and is called the Legendre's function of the second kind, thus

$$Q_n(\mu) = \frac{1.2.3\ldots n}{3.5\ldots 2n+1}\left\{\frac{1}{\mu^{n+1}} + \frac{(n+1)(n+2)}{2.2n+3}\frac{1}{\mu^{n+3}} + \ldots\right\}$$
$$= \frac{1.2.3\ldots n}{3.5\ldots 2n+1}\frac{1}{\mu^{n+1}}F\left(\frac{n+1}{2}, \frac{n+2}{2}, \frac{2n+3}{2}, \frac{1}{\mu^2}\right). \quad (28)$$

This function $Q_n(\mu)$, thus defined for mod $\mu > 1$, is of considerable importance in the potential theory. When mod $\mu < 1$, we may in a similar manner obtain two series in ascending powers of μ, one of which represents $P_n(\mu)$, and a certain linear function of the two series represents the analytical continuation of $Q_n(\mu)$ as defined above. The complete primitive of Legendre's equation is

$$u = AP_n(\mu) + BQ_n(\mu).$$

By the usual rule for obtaining the complete primitive of an ordinary differential equation of the second order when a particular integral is known, it can be shown that (27) is satisfied by

$$P_n(\mu) = \int^\mu\frac{d\mu}{(\mu^2-1)\{P_n(\mu)\}^2},$$

the lower limit being arbitrary.

From this form it can be shown that

$$Q_n(\mu)=\frac{1}{2}P_n(\mu)\log\frac{\mu+1}{\mu-1}-W_{n-1}(\mu),$$

where $W_{n-1}(\mu)$ is a rational integral function of degree $n-1$ in μ; it can be shown that this form is in agreement with the definition of $Q_n(\mu)$ by series, for the case mod $\mu>1$. In case mod $\mu<1$ it is convenient to use the symbol $Q_n(\mu)$ for

$$\frac{1}{2}P_n(\mu)\log\frac{1+\mu}{1-\mu}-W_{n-1}(\mu),$$

which is real when μ is real and between ± 1, the function $Q_n(\mu)$ in this case is not the analytical continuation of the function $Q_n(\mu)$ for mod $\mu>1$, but differs from it by an imaginary multiple of $P_n(\mu)$. It will be observed that $Q_n(1)$, $Q_n(-1)$ are infinite, and $Q_n(\infty)=0$. The function $W_{n-1}(\mu)$ has been expressed by Christoffel in the form

$$\frac{2n-1}{1.n}P_{n-1}(\mu)+\frac{2n-5}{3.n-1}P_{n-3}(\mu)+\frac{2n-9}{5.n-2}P_{n-5}(\mu)+\ldots,$$

and it can also be expressed in the form

$$\frac{1}{n}P_0(\mu)P_{n-1}(\mu)+\frac{1}{n-1}P_1(\mu)P_{n-2}(\mu)+\ldots+P_{n-1}(\mu)P_0(\mu).$$

It can easily be shown that the formula (28) is equivalent to

$$Q_n(\mu)=2^n n!\int_\mu^\infty\int_\mu^\infty\ldots\int_\mu^\infty\frac{(d\mu)^{n+1}}{(\mu^2-1)^{n+1}}$$

which is analogous to Rodrigue's expression for $P_n(\mu)$.

Another expression of a similar character is

$$Q_n(\mu)=(-1)^n\frac{2^n n!}{(2n)!}\frac{d^n}{d\mu^n}\left\{(\mu^2-1)^n\int_\mu^\infty\frac{d\mu}{\mu(\mu^2-1)^{n+1}}\right\}.$$

It can be shown that under the condition mod $\{u-\sqrt{(u^2-1)}\}>$ mod $\{\mu-\sqrt{(\mu^2-1)}\}$, the function $1/(\mu-u)$ can be expanded in the form $\Sigma(2n+1)P_n(u)Q_n(u)$; this expansion is connected with the definite integral formula for $Q_n(\mu)$ which was used by F. Neumann as a definition of the function $Q_n(\mu)$, this is

$$Q_n(\mu)=\frac{1}{2}\int_{-1}^{1}\frac{P_n(u)}{\mu-u}du,$$

which holds for all values of μ which are not real and between ± 1.

From Neumann's integral can be deduced the formula

$$Q_n(\mu)=\int_1^\infty\frac{d\psi}{\{\mu+\sqrt{(\mu^2-1)}.\cosh\psi\}^{n+1}},$$

which holds for all values of μ which are not real and between ± 1, provided the sign of $\sqrt{(\mu^2-1)}$ is properly chosen; when μ is real and greater than 1, $\sqrt{(\mu^2-1)}$ has its positive value.

By means of the substitution.

$$\{\mu+\sqrt{(\mu^2-1)}.\cosh\psi\}\{\mu-\sqrt{(\mu^2-1)}.\cosh\chi\}=1,$$

the above integral becomes

$$Q_n(\mu)=\int_0^{\chi_0}\{\mu-\sqrt{(\mu^2-1)}.\cosh\chi\}^n d\chi,\ \text{where}\ \chi_0=\frac{1}{2}\log_e\frac{\mu+1}{\mu-1}.$$

This formula gives a simple means of calculating $Q_n(\mu)$ for small values of n; thus

$$Q_0(\mu)=\int_0^{\chi_0}d\chi=\frac{1}{2}\log_e\frac{\mu+1}{\mu-1}.$$

$$Q_1(\mu)=\mu\chi_0-\sqrt{(\mu^2-1)}.\sinh\chi_0=\mu.\frac{1}{2}\log\frac{\mu+1}{\mu-1}-1.$$

Neumann's integral affords a means of establishing a relation between successive Q functions, thus

$$\begin{aligned}&nQ_n-(2n-1)\mu Q_{n-1}+(n-1)Q_{n-2}\\&=\frac{1}{2}\int_{-1}^{1}\frac{nP_n(u)+(n-1)P_{n-2}(u)-(2n-1)}{\mu-u}\mu P_{n-1}(u)du\\&=-\frac{1}{2}\int_{-1}^{1}(2n-1)P_{n-1}(u)=0.\end{aligned}$$

Again, it may similarly be proved that

$$\frac{dQ_{n+1}}{d\mu}-\frac{dQ_{n-1}}{d\mu}=(2n+1)Q_n.$$

19. *Legendre Associated Functions.*—Returning to the equation (26) satisfied by u_n^m the factor in the normal forms $\frac{r^n}{r^{-n-1}}\frac{\cos}{\sin}m\phi.u_n^m$, we shall consider the case in which n, m are positive integers, and $n\geqq m$. Let $u=(\mu^2-1)^{\frac{1}{2}m}v$, then it will be found that v satisfies the equation

$$(1-\mu^2)\frac{d^2v}{d\mu^2}-2(m+1)\mu\frac{dv}{d\mu}+(n-m)(n+m+1)v=0.$$

If, in Legendre's equation, we differentiate m times, we find

$$(1-\mu^2)\frac{d^{m+2}u}{d\mu^{m+2}}-2(m+1)\mu\frac{d^{m+1}u}{d\mu^{m+1}}+(n-m)(n+m+1)\frac{d^m u}{d\mu^m}=0;$$

it follows that $v=\frac{d^m u}{d\mu^m}$, hence $u_n^m=(\mu^2-1)^{\frac{1}{2}m}\frac{d^m u}{d\mu^m}$.

The complete solution of (26) is therefore

$$u=(\mu^2-1)^{\frac{1}{2}m}\left\{A\frac{d^mP_n(\mu)}{d\mu^m}+B\frac{d^mQ_n(\mu)}{d\mu^m}\right\};$$

when μ is real and lies between ± 1, the two functions

$$(1-\mu^2)^{\frac{1}{2}m}\frac{d^mP_n(\mu)}{d\mu^m},(1-\mu^2)^{\frac{1}{2}m}\frac{d^mQ_n(\mu)}{d\mu^m}$$

are called Legendre's associated functions of degree n, and order m, of the first and second kinds respectively. When μ is not real and between ± 1, the same names are given to the two functions

$$(\mu^2-1)^{\frac{1}{2}m}\frac{d^mP_n(\mu)}{d\mu^m},\ (\mu^2-1)^{\frac{1}{2}m}\frac{d^mQ_n(\mu)}{d\mu^m};$$

in either case the functions may be denoted by $P_n^m(\mu)$, $Q_n^m(\mu)$.

It can be shown that, when μ is real and between ± 1

$$\begin{aligned}P_n^m(\mu)&=\frac{(-1)^m}{2^n(n-m)!}\left(\frac{1+\mu}{1-\mu}\right)^{\frac{1}{2}m}\frac{d^n}{d\mu^n}\{(\mu-1)^{n+m}(\mu+1)^{n-m}\}\\&=\frac{1}{2^n(n-m)!}\left(\frac{1-\mu}{1+\mu}\right)^{\frac{1}{2}m}\frac{d^n}{d\mu^n}\{(\mu-1)^{n-m}(\mu+1)^{n+m}\}.\end{aligned}$$

In the same case, we find

$$P_n^{m+2}(\cos\theta)-2(m+1)\cot\theta\,P_n^{m+1}(\cos\theta)+(n-m)(n+m+1)P_n^m(\cos\theta)=0,$$

$$(n-m+2)P_{n+2}^m(\cos\theta)-(2n+3)\mu P_{n+1}^m(\cos\theta)+(n+m+1)P_n^m(\cos\theta)=0.$$

20. *Bessel's Functions.*—If we take for three orthogonal systems of surfaces a system of parallel planes, a system of co-axial circular cylinders perpendicular to the planes, and a system of planes through the axis of the cylinders, the parameters are z, ρ, ϕ, the cylindrical co-ordinates; in that case $H_1=1$, $H_2=1$, $H_3=1/\rho$, and the equation (25) becomes

$$\frac{\partial^2V}{\partial z^2}+\frac{\partial^2V}{\partial\rho^2}+\frac{1}{\rho}\frac{\partial V}{\partial\rho}+\frac{1}{\rho^2}\frac{\partial^2V}{\partial\phi^2}=0.$$

To find the normal functions which satisfy this equation, we put $V=ZR\Phi$, when Z is a function of z only, R of ρ only, and Φ of ϕ, the equation then becomes

$$\frac{1}{Z}\frac{d^2Z}{dz^2}+\frac{1}{R}\left(\frac{d^2R}{d\rho^2}+\frac{1}{\rho}\frac{dR}{d\rho}\right)+\frac{1}{\rho^2}\frac{1}{\Phi}\frac{d^2\Phi}{d\phi^2}=0.$$

That this may be satisfied we must have $\frac{1}{Z}\frac{d^2Z}{dz^2}$ constant, say $=k^2$, $\frac{1}{Z}\frac{d^2Z}{dz^2}$ constant, say $=-m^2$, and R, for which we write u, must satisfy the differential equation

$$\frac{d^2u}{d\rho^2}+\frac{1}{\rho}\frac{du}{d\rho}+\left(k^2-\frac{m^2}{\rho^2}\right)u=0,$$

it follows that the normal forms are $e^{\pm kz}\frac{\cos}{\sin}m\phi.u(k\rho)$, where $u(\rho)$ satisfies the equation

$$\frac{d^2u}{d\rho^2}+\frac{1}{\rho}\frac{du}{d\rho}+\left(1-\frac{m^2}{\rho^2}\right)u=0. \tag{29}$$

This is known as Bessel's equation of order m; the particular case

$$\frac{d^2u}{d\rho^2}+\frac{1}{\rho}\frac{du}{d\rho}+u=0, \tag{30}$$

corresponding to $m=0$, is known as Bessel's equation.

If we solve the equation (29) in series, we find by the usual process that it is satisfied by the series

$$\rho^m\left\{1-\frac{\rho^2}{2.2m+2}+\frac{\rho^4}{2.4.2m+2.2m+4}-\ldots\right\};$$

the expression

$$\frac{\rho^m}{2^m\Pi(m)}\left\{1-\frac{\rho^2}{2.2m+2}+\frac{\rho^4}{2.4.2m+2.2m+4}-\ldots\right\}$$

or

$$\sum_{n=0}^{\infty}\frac{(-1)^n\rho^{m+2n}}{2^{m+2n}\Pi(m+n)\Pi(n)}$$

is denoted by $J_m(\rho)$.

When $m=0$, the solution

$$1-\frac{\rho^2}{2^2}+\frac{\rho^4}{2^2.4^2}-\ldots$$

of the equation (30) is denoted by $J_0(\rho)$ or by $J(\rho)$.

The function $J_m(\rho)$ is called Bessel's function of order m, and $J_0(\rho)$ simply Bessel's function; the series are convergent for all finite values of ρ.

The equation (29) is unaltered by changing m into $-m$, it follows that $J_{-m}(\rho)$ is a second solution of (29). thus in general

$$u = AJ_m(\rho) + BJ_{-m}(\rho)$$

is the complete primitive of (29). However, in the most important case, that in which m is an integer, the solutions $J_{-m}(\rho)$, $J_m(\rho)$ are not distinct, for $J_{-m}(\rho)$ may be written in the form

$$\left(\frac{\rho}{2}\right)^{-m}\sum_{n=0}^{m-1}\frac{(-1)^n}{\Pi(n-m)\Pi(n)}\left(\frac{\rho}{2}\right)^{2n}$$
$$+(-1)^m\left(\frac{\rho}{2}\right)^m\sum_{p=0}^{\infty}\frac{(-1)^p}{\Pi(m+p)\Pi(p)}\left(\frac{\rho}{2}\right)^{2p}$$

now $\Pi(n-m)$ is infinite when m is an integer, and $n < m$; thus the first part of the expression vanishes, and the second part is $(-1)^m J_m(\rho)$, hence when m is an integer $J_{-m}(\rho) = (-1)^m J_m(\rho)$, and the second solution remains to be found.

Bessel's Functions of the Second Kind.—When m is not a real integer, we have seen that any linear function of $J_m(\rho)$, $J_{-m}(\rho)$ satisfies the equation of order m. The Bessel's function of the second kind of order m is defined as the particular linear function

$$\pi e^{m\pi\iota}\frac{J_{-m}(\rho) - \cos m\pi \,.\, J_m(\rho)}{\sin 2m\pi},$$

and may be denoted by $Y_m(\rho)$. This definition has the advantage of giving a meaning to $Y_m(\rho)$ in the case in which m is an integer, for it may be evaluated as a limiting form 0/0, and the limit will satisfy the equation (29). The only failing case is when m is half an odd integer; in that case we take $\cos m\pi \; Y_m(\rho)$ as a second finite solution of the differential equation.

When m is an integer, we have

$$Y_m(\rho) = (-1)^m\frac{\pi}{2}\left\{\frac{dJ_{-m-\epsilon}}{d\epsilon} - (-1)^m\frac{dJ_{m+\epsilon}}{d\epsilon}\right\}\epsilon = 0$$

on carrying out the differentiations, and proceeding to the limit we find

$$Y_m(\rho) = J_m(\rho)\log\frac{2}{\rho} + \frac{1}{2}\left(\frac{\rho}{2}\right)^m\sum_{n=0}^{\infty}[\dagger(n)+\dagger(m+n)]\frac{(-1)^n}{\Pi n(m+)\Pi(n)}\left(\frac{\rho}{2}\right)^{2n}$$
$$+\frac{1}{2}\left(\frac{\rho}{2}\right)^{-m}\sum_{n=0}^{m-1}\frac{\Pi(m-n-1)}{\Pi(n)}\left(\frac{\rho}{2}\right)^{2n}$$

where $\dagger(n)$ denotes $\Pi'(n)/\Pi(n)$.

When $m=0$ we have the second solution of (30) given by

$$Y_0(\rho) = J_0(\rho)\log\frac{2}{\rho} + \sum_{0}^{\infty}\frac{(-1)^n\dagger(n)}{\Pi(n)\Pi(n)}\left(\frac{\rho}{2}\right)^{2n}.$$

21. *Relations between Bessel's Functions of Different Orders.*—Since $e^z \begin{smallmatrix}\cos\\ \sin\end{smallmatrix} m\phi \cdot u_m(\rho)$ satisfies Laplace's equation, it follows that $\begin{smallmatrix}\cos\\ \sin\end{smallmatrix} m\phi . u_m(\rho)$ satisfies the differential equation

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + u = 0. \tag{31}$$

The linear character of this equation shows that if u is any solution

$$f\left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}\right)u$$

is also one, f denoting a rational integral function of the operators. Let ξ, η denote $x+\iota y$, $x-\iota y$, then since $\rho^{-m}\xi^m u_m(\sqrt{\xi\eta})$ satisfies the differential equation, so also does

$$\xi^m\frac{\partial^p}{\partial\eta^p}\{\rho^{-m}u_m(\sqrt{\xi\eta})\},$$

or

$$\xi^{m+p}\frac{d^p}{d(\rho^2)^p}\{\rho^{-m}u_m(\rho)\},$$

thus we have

$$u_{m+p} = C\rho^{m+p}\frac{d^p}{d(\rho^2)^p}\left\{\frac{u_m(\rho)}{\rho_m}\right\}$$

where C is a constant. If $u_m(\rho) = J_m(\rho)$, we have $u_{m+p} = J_{m+p}(\rho)$, and by comparing the coefficients of ρ^{m+p}, we find $C = (-2)^p$, hence

$$J_{m+p}(\rho) = (-2)^p\rho^{m+p}\frac{d^p}{d(\rho^2)^p}\{\rho^{-m}J_m(\rho)\},$$

and changing m into $-m$, we find

$$J_{p-m}(\rho) = (-2)^p\rho^{p-m}\frac{d^p}{d(\rho^2)^p}\{\rho^m J_{-m}(\rho)\}.$$

In a similar manner it can be proved that

$$J_{m-p}(\rho) = 2^p\rho^{p-m}\frac{d^p}{d(\rho^2)^p}\{\rho^m J_m(\rho)\}.$$

From the definition of $Y_m(\rho)$, and applying the above analysis, we prove that

$$Y_{m+p}(\rho) = (-2)^p\rho^{m+p}\frac{d^p}{d(\rho^2)^p}\{\rho^{-m}Y_m(\rho)\}$$

and

$$Y_{m-p}(\rho) = 2^p\rho^{p-m}\frac{d^p}{d(\rho^2)^p}\{\rho^m Y_m(\rho)\}.$$

As particular cases of the above formulae, we find

$$J_p(\rho) = (-2\rho)^p\frac{d^p}{d(\rho^2)^p}J_0(\rho),\quad Y_p(\rho) = (-2\rho)^p\frac{d^p}{d(\rho^2)^p}Y_0(\rho)$$
$$J_1(\rho) = -\frac{dJ_0(\rho)}{d\rho},\quad Y_1(\rho) = -\frac{dY_0(\rho)}{d\rho}.$$

22. *Bessel's Functions as Coefficients in an Expansion.*—It is clear that $e^{\iota\rho\cos\phi} = e^{\iota x}$ or $e^{\iota\rho\sin\phi} = e^{\iota y}$ satisfy the differential equation (31), hence if these exponentials be expanded in series of cosines and sines of multiples of ϕ, the coefficients must be Bessel's functions, which it is easy to see are of the first kind. To expand $e^{\iota\rho\sin\phi}$, put $e^{\iota\phi} = t$, we have then to expand $e^{\frac{1}{2}\rho(t-t^{-1})}$ in powers of t. Multiplying together the two absolutely convergent series

$$e^{\frac{1}{2}\rho t} = \sum\frac{1}{m!}\left(\frac{\rho}{2}\right)^m t^m,\quad e^{-\frac{1}{2}\rho t^{-1}} = \sum\frac{(-1)^m}{m!}\left(\frac{1}{2\rho}\right)^m t_m,$$

we obtain for the coefficient of t^m in the product

$$\frac{\rho^m}{2^m m!}\left\{1 - \frac{\rho^2}{2.2m+2} + \frac{\rho^4}{2.4.2m+2.2m+4} - \dots\right\}\text{ or } J_m(\rho),$$

hence

$$\begin{aligned}e^{\frac{1}{2}\rho(t-t^{-1})} &= J_0(\rho) + tJ_1(\rho) + \dots + t^m J_m(\rho) + \dots \\ &\quad - t^{-1}J_1(\rho) + \dots + (-1)^m t^{-m}J_m(\rho) \\ &= \sum_{-\infty}^{\infty} t^m J_m(\rho)\end{aligned} \tag{32}$$

the Bessel's functions were defined by Schlömilch as the coefficients of the powers of t in the expansion of $e^{\frac{1}{2}\rho(t-t^{-1})}$, and many of the properties of the functions can be deduced from this expansion. By differentiating both sides of (32) with respect to t, and equating the coefficients of t^{m-1} on both sides, we find the relation

$$J_{m-1}(\rho) + J_{m+1}(\rho) = \frac{2m}{\rho}J_m(\rho),$$

which connects three consecutive functions. Again, by differentiating both sides of (32) with respect to ρ, and equating the coefficients of corresponding terms, we find

$$2\frac{dJ_m(\rho)}{d\rho} = J_{m-1}(\rho) - J_{m+1}(\rho).$$

In (32), let $t = e^{\iota\phi}$, and equate the real and imaginary parts, we have then

$$\cos(\rho\sin\phi) = J_0(\rho) + 2J_2(\rho)\cos 2\phi + 2J_3(\rho)\cos 3\phi + \dots$$
$$\sin(\rho\sin\phi) = 2J_1(\rho)\sin\phi + 2J_3(\rho)\sin 3\phi + \dots$$

we obtain expansions of $\cos(\rho\cos\phi)$, $\sin(\rho\cos\phi)$, by changing ϕ into $\frac{1}{2}-\phi$. On comparing these expansions with Fourier's series, we find expressions for $J_m(\rho)$ as definite integrals, thus

$$J_0(\rho) = \frac{1}{\pi}\int_0^\pi\cos(\rho\sin\phi)d\phi,\quad J_m(\rho) = \frac{1}{\pi}\int_0^\pi\cos(\rho\sin\phi)\cos m\phi d\phi\ (m\text{ even})$$

$$J_m(\rho) = \frac{1}{\pi}\int_0^\pi\sin(\rho\sin\phi)\sin m\phi d\phi\ (m\text{ odd}).$$

It can easily be deduced that when m is any positive integer

$$J_m(\rho) = \frac{1}{\pi}\int_0^\pi\cos(m\phi - \rho\sin\phi)d\phi.$$

23. *Bessel's Functions as Limits of Legendre's Functions.*—The system of orthogonal surfaces whose parameters are cylindrical coordinates may be obtained as a limiting case of those whose parameters are polar co-ordinates, when the centre of the spheres moves off to an indefinite distance from the portion of space which is contemplated. It would therefore be expected that the normal forms $e^{\pm\lambda z}J_m(\lambda\rho)\begin{smallmatrix}\cos\\ \sin\end{smallmatrix}m\phi$ would be derivable as limits of $\begin{smallmatrix}r^n\\ r^{-n-1}\end{smallmatrix}P_n^m(\cos\theta)\begin{smallmatrix}\cos\\ \sin\end{smallmatrix}m\phi$, and we shall show that this is actually the case. If O be the centre of the spheres, take as new origin a point C on the axis of z, such that $OC = a$; let P be a point whose polar co-ordinates are r, θ, ϕ referred to O as origin, and cylindrical co-ordinates ρ, z, ϕ referred to C as origin; we have

$$\rho = r\sin\theta,\ z = r\cos\theta - a,\text{ hence }\left(\frac{r}{a}\right)^n P_n(\cos\theta) = \sec^n\theta\left(1+\frac{z}{a}\right)^n P_n(\cos\theta).$$

Now let O move off to an infinite distance from C, so that a becomes infinite, and at the same time let n become infinite in such a way that n/a has a finite value λ. Then

$$\mathrm{L}\sec^n\theta=\mathrm{L}\left(\sec\frac{\rho}{a}\right)^{\lambda a}=1,\ \mathrm{L}\left(1+\frac{z}{a}\right)^n=e^{\lambda z},$$

and it remains to find the limiting value of $P_n(\cos\theta)$. From the series (15), it may be at once proved that

$$P_n(\cos\theta)=1-\frac{(n+1)n}{1^2}\left(\sin\frac{\theta}{2}\right)^2+\dots$$
$$+(-1)^m\delta\frac{(n+m)\dots(n-m+1)}{1^2.2^2.m^2}\left(\sin\frac{\theta}{2}\right)^{2m}$$

where δ is some number numerically less than unity and m is a fixed finite quantity sufficiently large; on proceeding to the limit, we have

$$\mathrm{L}P_n\left(\cos\frac{\lambda\rho}{n}\right)=1-\frac{\lambda^2\rho^2}{2^2}+\frac{\lambda^4\rho^4}{2^2.4^2}-\dots+(-1)^m\delta_1\frac{\lambda^{2m}\rho^{2m}}{2^2.4^2.(2m)^2}$$

where δ_1 is less than unity.

Hence

$$\underset{n=\infty}{\mathrm{L}}\ P_n\left(\cos\frac{\lambda\rho}{n}\right)=J_0(\lambda\rho).$$

Again, since

$$P_n^m(\cos\rho)=\sin^m\theta\frac{d^mP_n(\cos\theta)}{d(\cos\theta)^m},$$

we have

$$\mathrm{L}n^{-m}P_n^m\left(\cos\frac{\rho}{n}\right)=\mathrm{L}\frac{\rho^m}{n^{2m}}\frac{d^mP_n\left(\cos\frac{\rho}{n}\right)}{d\left(-\frac{\rho^2}{2n^2}\right)^m}$$
$$=(-2)^m\rho^m\frac{d_mJ_0(\rho)}{d(\rho^2)^m}$$

hence

$$\underset{n=\infty}{\mathrm{L}}\ n^{-m}P_n^m\left(\cos\frac{\rho}{n}\right)=J_m(\rho).$$

It may be shown that $Y_0(\rho)$ is obtainable as the limit of $Q_n\left(\cos\frac{\rho}{n}\right)$ the zonal harmonic of the second kind; and that

$$Y_m(\rho)=\mathrm{L}n^{-m}Q_n^m\left(\cos\frac{\rho}{n}\right).$$

24. *Definite Integral Solutions of Bessel's Equation.*—Bessel's equation of order m, where m is unrestricted, is satisfied by the expression $\rho^m\int e^{\iota\rho t}(t^2-1)^{m-\frac{1}{2}}dt$, where the path of integration is either a curve which is closed on the Riemann's surface on which the integrand is represented, or is taken between limits, at each of which $e^{\iota\rho t}(t^2-1)^{m+\frac{1}{2}}$ is zero. The equation is also satisfied by the expression $\int e^{\frac{1}{2}\rho(t-t^{-1})}t^{-m-1}dt$ where the integral is taken along a closed path as before, or between limits at each of which $e^{\frac{1}{2}\rho(t-t^{-1})}t^{-m-1}$ vanishes.

The following definite integral expressions for Bessel's functions are derivable from these fundamental forms.

$$J_m(\rho)=\frac{1}{\Pi(-\frac{1}{2})\Pi(m-\frac{1}{2})}\left(\frac{\rho}{2}\right)^m\int_0^\pi e^{\iota\rho\cos\phi}\sin^{2m}\phi d\phi$$

where the real part of $m+\frac{1}{2}$ is positive.

$$Y_m(\rho)+\tfrac{1}{2}\pi\iota.e^{m\pi\iota}\sec m\pi.J_m(\rho)$$
$$=\frac{\Pi(-\frac{1}{2}-m)}{\Pi(-\frac{1}{2})}\left(\frac{\rho}{2}\right)^m\int_0^{\infty+\frac{1}{2}\pi\iota}e^{\iota\rho\cosh\phi}\sinh^{2m}\phi d\phi$$

where the real parts of $m+\frac{1}{2}$, ρ are positive; if ρ is purely imaginary and positive the upper limit may be replaced by ∞.

$$Y_m(\rho)-\tfrac{1}{2}\pi\iota.e^{m\pi\iota}\sec m\pi.J_m(\rho)$$
$$=e^{2m\pi\iota}\frac{\Pi(-\frac{1}{2}-m)}{\Pi(-\frac{1}{2})}\left(\frac{\rho}{2}\right)^m\int_0^{\infty-\frac{1}{2}\pi\iota}e^{-\iota\rho\cosh h\phi}\sinh^{2m}\phi d\phi$$

under the same restrictions as in the last case; if ρ is a negative imaginary number, we may put ∞ for the upper limit.

If ρ is real and positive

$$J_0(\rho)=\frac{2}{\pi}\int_0^\infty\sin(\rho\cosh\phi)d\phi$$
$$Y_0(\rho)=\int_0^\infty\cos(\rho\cosh\phi)d\phi.$$

25. *Bessel's Functions with Imaginary Argument.*—The functions with purely imaginary argument are of such importance in connexion with certain differential equations of physics that a special notation has been introduced for them. We denote the two solutions of the equation

$$\frac{d^2u}{dr^2}+\frac{1}{r}\frac{du}{dr}-u=0$$

by $I_0(r)$, $K_0(r)$ when

$$I_0(r)=J_0(\iota r)=1+\frac{r^2}{2^2}+\frac{r^2}{2^2.4^2}+\dots$$
$$=\frac{1}{\pi}\int_0^\pi\cosh(r\cos\phi)d\phi,$$

and

$$K_0(r)=Y_0(\iota r)+\frac{1}{2}\iota\pi J_0(\iota r)=\int_0^\infty e^{-r\cos h\phi}d\phi=\int_0^\infty\cos(r\sinh\psi)d\psi.$$

The particular integral $K_0(r)$ is so chosen that it vanishes when r is real and infinite; it is also represented by

$$\int_0^\infty\frac{\cos v}{\sqrt{(v^2+r^2)}}dv,$$

and by

$$\int_1^\infty\frac{e^{-ru}}{\sqrt{(u^2-1)}}du.$$

The solutions of the equation

$$\frac{du^2}{dr^2}+\frac{1}{r}\frac{du}{dr}-\left(1+\frac{m^2}{r^2}\right)u=0$$

are denoted by $I_m(r)$, $K_m(r)$, where

$$I_m(r)=\frac{r^m}{2^m\Pi(m)}\left\{1+\frac{\rho^2}{2.2m+2}+\frac{\rho^4}{2.4.2m+2.2m+4}+\dots\right\}$$
$$=(2r)^m\frac{d^m}{d(r^2)^m}I_0(r),$$

when m is an integer, and

$$K_m(r)=(2r)^m\frac{d^m}{d(r^2)^m}K_0(r)=e^{-\frac{1}{2}m\pi\iota}\left\{Y_m(\iota r)+\frac{1}{2}\iota\pi J_m(\iota r)\right\}.$$

We find also

$$I_m(r)=\frac{r^m}{1.3.5\dots(2m-1)}\frac{1}{\pi}\int_0^\pi\cosh(r\cos\phi)\sin^{2m}\phi d\phi$$
$$K_m(r)=\frac{(-1)^mr^m}{1.3.5\dots(2m-1)}\int_0^\infty e^{-r\cosh\phi}\sinh^{2m}\phi d\phi$$
$$=(-1)^m3.5\dots\overline{2m-1}r^m\int_0^\infty\frac{\cos u}{(u^2+r^2)^{m+\frac{1}{2}}}du.$$

26. *The Asymptotic Series for Bessel's Functions.*—It may be shown, by means of definite integral expressions for the Bessel's functions, that

$$J_m(\rho)=\sqrt{\frac{2}{\pi\rho}}\left\{P\cos\left(\frac{m\pi}{2}+\frac{\pi}{4}-\rho\right)+Q\sin\left(\frac{m\pi}{2}+\frac{\pi}{4}-\rho\right)\right\}$$
$$Y_m(\rho)=\sqrt{\frac{\pi}{2\rho}}e^{m\pi\iota}\sec m\pi\left\{P\sin\left(\frac{m\pi}{2}+\frac{\pi}{4}-\rho\right)-Q\cos\left(\frac{m\pi}{2}+\frac{\pi}{4}-\rho\right)\right\}$$

where P and Q denote the series

$$P=1-\frac{(4m^2-1^2)(4m^2-3^2)}{1.2.(8\rho)^2}$$
$$+\frac{(4m^2-1^2)(4m^2-3^2)(4m^2-5^2)(4m^2-7^2)}{1.2.3.4(8\rho)^4}-\dots$$
$$Q=\frac{4m^2-1^2}{1.8\rho}-\frac{(4m^2-1^2)(4m^2-3^2)(4m^2-5^2)}{1.2.3.(8\rho)^3}+\dots$$

These series for P, Q are divergent unless m is half an odd integer, but it can be shown that they may be used for calculating the values of the functions, as they have the property that if in the calculation we stop at any term, the error in the value of the function is less than the next term; thus in using the series for calculation, we must stop at a term which is small. In such series the remainder after n terms has a minimum for some value of n, and for greater values of n increases beyond all limits; such series are called semi-convergent or asymptotic.

We have as particular cases of such series:—

$$J_0(\rho)=\sqrt{\frac{2}{\pi\rho}}\cos\left(\frac{\pi}{4}-\rho\right)\left\{1-\frac{1^2.3^2}{1.2(8\rho)^2}+\frac{1^2.3^2.5^2.7^2}{1.2.3.4(8\rho)^4}-\dots\right\}$$
$$-\sqrt{\frac{2}{\pi\rho}}\sin\left(\frac{\pi}{4}-\rho\right)\left\{\frac{1^2}{1.8\rho}-\frac{1^2.3^2.5^2}{1.2.3(8\rho)^3}+\dots\right\}$$

when m is an integer,

$$K_m(r)=(-1)^m\sqrt{\frac{\pi}{2r}}e^{-r}\left\{1+\frac{4m^2-1^2}{1.8r}+\frac{(4m^2-1^2)(4m^2-3^2)}{1.2(8r)^2}+\dots\right\}$$
$$I_m(r)=\frac{1}{\sqrt{2\pi r}}e^r\left\{1-\frac{4m^2-1^2}{1.8r}+\frac{(4m^2-1^2)(4m^2-3^2)}{1.2(8r)^2}-\dots\right\}$$

27. *The Bessel's functions of degree half an odd integer* are of special

importance in connexion with the differential equations of physics. The two equations

$$\frac{\partial u}{\partial t}=k\nabla^2 u,\ \frac{\partial^2 u}{\partial t^2}=k^2\nabla^2 u,$$

are reducible by means of the substitutions $u=e^{-kt}v$, $u=e^{\iota kt}v$ to the form $\nabla^2 v+v=0$. If we suppose v to be a function of r only, this last differential equation takes the form

$$\frac{d^2(vr)}{dr^2}+vr=0,$$

so that v has the values

$$\sin r/r,\ \cos r/r;$$

in order to obtain more general solutions of the equation $\nabla^2 v+v=0$, we may operate on

$$\sin r/r, \cos r/r$$

with the operator

$$Y_n\left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z}\right),$$

where $Y_n(x, y, z)$ is any spherical solid harmonic of degree n. The result of the operation may be at once obtained by taking $Y_n(x, y, z)$ for $f_n(x, y, z)$ in the theorem (7′), we thus find as solutions, of $\nabla^2 v+v=0$, the expressions

$$Y_n(x, y, z)\frac{d^n}{d(r^2)^n}\frac{\sin r}{r},\ Y_n(x, y, z)\frac{d^n}{d(r^2)^n}\frac{\cos r}{r}.$$

By recurring to the definition of the function $J_m(r)$, we see that

$$J_{\frac{1}{2}}(r)=\sqrt{\frac{2\rho}{\pi}}\left\{1-\frac{r^2}{2\cdot 3}+\frac{r^4}{2\cdot 3\cdot 4\cdot 5}-\dots\right\}=\sqrt{\frac{2}{\pi}}\frac{\sin r}{\sqrt{r}};$$

thus

$$r^{-\frac{1}{2}}J_{\frac{1}{2}}(r)=\sqrt{\frac{2}{\pi}}\frac{\sin r}{r}.$$

Using the relation between Bessel's functions whose orders differ by an integer, we have

$$J_{n+\frac{1}{2}}(r)=(-2)^n r^{n+\frac{1}{2}}\frac{d^n}{d(r^2)^n}\frac{J_{\frac{1}{2}}(r)}{\sqrt{r}}=(-2)^n\sqrt{\frac{2}{\pi}}r^{n+\frac{1}{2}}\frac{d^n}{d(r^2)^n}\frac{\sin r}{r}.$$

It may be shown at once that

$$r^{n+\frac{1}{2}}\frac{d^n}{d(r^2)^n}\frac{\cos r}{r}$$

is a second solution of Bessel's equation of order $n+\frac{1}{2}$; thus the differential equation $\nabla^2 v+v=0$ is satisfied by the expression

$$Y_n(x, y, z)\frac{J_{n+\frac{1}{2}}(r)}{r^{n+\frac{1}{2}}},$$

and by the corresponding expression with a second solution of Bessel's equation instead of $J_{n+\frac{1}{2}}(r)$; if $S_n(\mu, \phi)$ denotes a surface harmonic of degree n, the expression

$$S_n(\mu, \phi)\frac{1}{\sqrt{r}}J_{n+\frac{1}{2}}(r)$$

is a solution of the equation $\nabla^2 v+v=0$.

The Bessel's functions of degree half an odd integer are the only ones which are expressible in a closed form involving no transcendental functions other than circular functions. It will be observed that in this case the semi-convergent series for J_m becomes a finite one as the expressions P, Q then break off after a finite number of terms.

28. *The Zeros of Bessel's Functions.*—The determination of the position of the zeros of the Bessel's functions, and the values of the argument at which they occur, have been investigated by Hurwitz (*Math. Ann.* vol. xxxiii.), and more completely by H. M. Macdonald (*Proc. Lond. Math. Soc.* vols. xxix., xxx.). It has been shown that the zeros of $J_n(z)/z^n$ are all real and associated with the singular point at infinity when n is real and >-1, and that all the real zeros of $J_n(z)/z^n$ when n is real and <-1, and not an integer, are associated with the essential singularity at infinity. When n is a negative integer $-m$, $J_n(z)/z^n$ has, in addition, $2m$ real zeros coincident at the origin. When $n=-m-v$, m being a positive integer, and $1>v>0$, $J_n(z)/z^n$ has a finite number $2m$ of zeros which are not associated with the essential singularity. If n is real, and starts with any positive value, the zeros nearest the origin approach it as n diminishes, two of them reaching it when $n=-1$, and two more reach it whenever n passes through a negative integral value; these zeros then become complex for values of n not integral. The zeros of $J_n(z)/z^n$ are separated by those of $J_{n+1}(z)/z^n$, one zero of the latter, and one only, lies between two consecutive zeros of $J_n(z)/z^n$. When n is real and >-1, all the zeros of $J_n(z)/z^n$ are given by a formula due to Stokes; the m^{th} positive zero in order of magnitude is given by

$$a=\frac{4n^2-1}{8a}-\frac{4(4n^2-1)(28n^2-31)}{3\cdot(8a)^3}-\&c.,$$

where $a=\frac{1}{4}\pi(2n+4m-1)$. It has been shown by Macdonald that the function $K_n(z)$ has no real zeros unless $n=2k+\frac{1}{2}$ where k is an integer, when it has one real negative zero; and that $K_n(z)$ has no purely imaginary zeros, and no zero whose real part is positive, other than those at infinity. When $1>n>0$, $K_n(z)$ has no zeros other than those at infinity, when $2>n>1$, it has one zero whose real part is negative, and when $m+1>n>m$ where m is an integer, there are m zeros whose real parts are negative. When n is an integer, $K_n(z)$ has n zeros with negative real parts.

29. *Spheroidal Harmonics.*—For potential problems in which the boundary is an ellipsoid of revolution, the co-ordinates to be used are r, θ, ϕ where in the case of a prolate spheroid

$$x=c\sqrt{r^2-1}\sin\theta\cos\phi,\ y=c\sqrt{r^2-1}\sin\theta\sin\phi,\ z=cr\cos\theta,$$

the surfaces $r=r_0$, $\theta=\theta_0$, $\phi=\phi_0$ are confocal prolate spheroids, confocal hyperboloids of revolution, and planes passing through the axis of revolution. We may suppose r to range from 1 to ∞, θ from 0 to π, and ϕ from 0 to 2π, every point in space has then unique co-ordinates r, θ, ϕ.

For oblate spheroids, the corresponding co-ordinates are r, θ, ϕ given by

$$x=c\sqrt{r^2+1}\sin\theta\cos\phi,\ y=c\sqrt{r^2+1}\sin\theta\sin\phi,\ z=cr\cos\theta,$$

where

$$0\leq r\leq\infty,\ 0\leq\theta\leq\pi,\ 0\leq\phi\leq 2\pi;$$

these may be obtained from those for the prolate spheroid by changing c into $-\iota c$, and r into ιr.

Taking the case of the prolate spheroid, Laplace's equation becomes

$$\frac{\partial}{\partial r}\left\{(r^2-1)\frac{\partial V}{\partial r}\right\}+\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial V}{\partial\theta}\right)+\frac{r^2-\cos^2\theta}{(r^2-1)\sin^2\theta}\frac{\partial^2 V}{\partial\phi^2}=0,$$

and it will be found that the normal solutions are

$$\left.\begin{matrix}P_n^m(r)\\ Q_n^m(r)\end{matrix}\right\}\left.\begin{matrix}P_n^m(\cos\theta)\\ Q_n^m(\cos\theta)\end{matrix}\right\}\begin{matrix}\cos\\ \sin\end{matrix}m\phi.$$

For the space inside a bounding spheroid the appropriate normal forms are $P_n^m(r)P_n^m(\cos\theta)\frac{\cos}{\sin}m\phi$, where n, m are positive integers, and for the external space

$$Q_n^m(r)P_n^m(\cos\theta)\frac{\cos}{\sin}m\phi.$$

For the case of an oblate spheroid, $P_n^m(\iota r)$, $Q_n^m(\iota r)$, take the place of $P_n^m(r)$, $Q_n^m(r)$.

30. *Toroidal Functions.*—For potential problems connected with the anchor-ring, the following co-ordinates are appropriate: If A, B are points at the extremities of a diameter of a fixed circle, and P is any point in the plane PAB which is perpendicular to the plane of the fixed circle, let $P=\log(AP/BP)$, $\theta=\angle APB$, and let ϕ be the angle the plane APB makes with a fixed plane through the axis of the circle. Let θ be restricted to lie between $-\pi$ and π, a discontinuity in its value arising as we pass through the circle, so that within the circumference θ is π on the upper side of the circle, and $-\pi$ on the lower side; θ is zero in the plane of the circle outside the circumference; ρ may have any value between $-\infty$ and ∞. and ϕ any value between 0 and 2π. The position of a point is then uniquely represented by the co-ordinates ρ, θ, ϕ, which are the parameters of a system of tores with the fixed circle as limiting circle, a system of bowls with the fixed circle as common rim, and a system of planes through the axis of the tores. If x, y, z are the co-ordinates of a point referred to axes, two of which x, y are in the plane of the circle and the third along its axis, we find that

$$x=\frac{a\sinh\rho}{\cosh\rho-\cos\theta}\cos\phi,\ y=\frac{a\sinh\rho}{\cosh\rho-\cos\theta}\sin\phi,\ z=\frac{a\sin\theta}{\cosh\rho-\cos\theta},$$

where a is the radius of the fixed circle.

Laplace's equation reduces to

$$\frac{\partial}{\partial\rho}\left\{\frac{\sinh\rho}{P^2}\frac{\partial V}{\partial\rho}\right\}+\frac{\partial}{\partial\theta}\left\{\frac{\sinh\rho}{P^2}\frac{\partial V}{\partial\theta}\right\}+\frac{1}{P^2\sinh\rho}\frac{\partial^2 V}{\partial\phi^2}=0,$$

when P denotes $\sqrt{(\cosh\rho-\cos\theta)}$. It can be shown that this equation is satisfied by

$$\sqrt{(\cosh\rho-\cos\theta)}\begin{matrix}P_{n-\frac{1}{2}}^m(\cosh\rho)\\ Q_{n-\frac{1}{2}}^m(\cosh\rho)\end{matrix}\begin{matrix}\cos\\ \sin\end{matrix}n\theta\begin{matrix}\cos\\ \sin\end{matrix}m\phi,$$

the functions $P_{n-\frac{1}{2}}^m(\cosh\rho)$, $Q_{n-\frac{1}{2}}^m(\cosh\rho)$ required for the potential problems, are associated Legendre's functions of degree $n-\frac{1}{2}$, half an odd integer, of integral order m, and of argument real and greater than unity; these are known as toroidal functions. For the space external to a boundary tore the function $Q_{n-\frac{1}{2}}^m(\cosh\rho)$ must be used, and for the internal space $P_{n-\frac{1}{2}}^m(\cosh\rho)$.

The following expressions may be given for the toroidal functions:—

$$\mathrm{P}^m_{n-\frac{1}{2}}(\cosh\rho)=\frac{(-1)^m}{\pi}\frac{\Pi(n-\frac{1}{2})}{\Pi(n-m-\frac{1}{2})}\int_0^\pi\frac{\cos m\phi}{(\cosh\rho+\sinh\rho\cos\phi)^{n+\frac{1}{2}}}d\phi$$

$$=\frac{1}{\pi}\frac{\Pi(n+m-\frac{1}{2})}{\Pi(n-\frac{1}{2})}\int_0^\pi(\cosh\rho+\sinh\rho\cos\phi)^{n-\frac{1}{2}}\cos m\phi d\phi.$$

$$\mathrm{P}_{n-\frac{1}{2}}(\cosh\rho)=\frac{2}{\pi}\int_0^\rho\frac{\cosh n\phi}{\sqrt{2\cosh\rho-2\cosh\phi}}d\phi.$$

$$\mathrm{Q}_{n-\frac{1}{2}}(\cosh\rho)=(-1)^m\frac{\Pi(n+m-\frac{1}{2})}{\Pi(n-\frac{1}{2})}\int_0^{\log\coth\frac{1}{2}\rho}(\cosh\rho-\sinh\rho\cosh w)^{n-\frac{1}{2}}\cosh mw dw$$

$$=(-1)^m\frac{1}{\pi}2^m\Pi(m-\tfrac{1}{2})\Pi(-\tfrac{1}{2})\sinh^m\rho\int_0^\pi\frac{\cos n\phi}{(2\cosh\rho-2\cos\phi)^{m+\frac{1}{2}}}d\phi.$$

The relations between functions for three consecutive values of the degree or the order are

$$2n\cosh\rho\mathrm{P}^m_{n-\frac{1}{2}}(\cosh\rho)-(n-m+\tfrac{1}{2})\mathrm{P}^m_{n+\frac{1}{2}}(\cosh\rho)$$
$$-(n+m-\tfrac{1}{2})\mathrm{P}^m_{n-\frac{1}{2}}(\cosh\rho)=0$$

$$\mathrm{P}^{m+2}_{n-\frac{1}{2}}(\cosh\rho)+2(m+1)\coth\rho\mathrm{P}^{m+1}_{n-\frac{1}{2}}(\cosh\rho)$$
$$-(n-m-\tfrac{1}{2})(n+m+\tfrac{1}{2})\mathrm{P}^m_{n-\frac{1}{2}}(\cosh\rho)=0,$$

with relations identical in form for the functions $\mathrm{Q}^m_{n-\frac{1}{2}}(\cosh\rho)$.

The function $\mathrm{Q}_{n-\frac{1}{2}}(\cosh\rho)$ is expansible in the form

$$\frac{\Pi(n-\frac{1}{2})\Pi(-\frac{1}{2})}{\Pi(n)}e^{-(n+\frac{1}{2})\rho}\mathrm{F}(\tfrac{1}{2},n+\tfrac{1}{2},n+1,e^{-2\rho}),$$

which is useful for calculation of the function when ρ is not small. $\mathrm{P}_{n-\frac{1}{2}}(\cosh\rho)$ can also be expressed in terms of $e^{-\rho}$ by a somewhat complicated formula.

31. *Ellipsoidal Harmonics.*—In order to treat potential problems in which the boundary surface is an ellipsoid, Lamé took as co-ordinates the parameters ρ, μ, ν of systems of confocal ellipsoids, hyperboloids of one sheet, and of two sheets; these co-ordinates are three roots of the equation

$$\frac{x^2}{t^2}+\frac{y^2}{t^2-h^2}+\frac{z^2}{t^2-k^2}=1,\ (k>h);$$

we thence find that

$$x=\frac{\rho\mu\nu}{hk},\ y=\frac{\sqrt{\rho^2-h^2}\sqrt{\mu^2-h^2}\sqrt{h^2-\nu^2}}{h\sqrt{k^2-h^2}},\ z=\frac{\sqrt{\rho^2-k^2}\sqrt{k^2-\mu^2}\sqrt{k^2-\nu^2}}{k\sqrt{k^2-h^2}}$$

where $\infty\geqq\rho^2\geqq h^2,\ k^2\leqq\mu^2\leqq h^2$, and $k^2\geqq\nu^2\geqq 0$.

We find from these values of x, y, z

$$(dx)^2+(dy)^2+(dz)^2=\frac{(\rho^2-\mu^2)(\rho^2-\nu^2)}{(\rho^2-h^2)(\rho^2-k^2)}(d\rho)^2+\frac{(\rho^2-\mu^2)(\mu^2-\nu^2)}{(\mu^2-h^2)(k^2-\mu^2)}(d\mu)^2$$
$$+\frac{(\rho^2-\nu^2)(\mu^2-\nu^2)}{(h^2-\nu^2)(k^2-\nu^2)}(d\nu)^2,$$

and on applying the general transformation of Laplace's equation that equation becomes

$$(\mu^2-\nu^2)\frac{\partial^2\mathrm{V}}{\partial\xi^2}+(\rho^2-\nu^2)\frac{\partial^2\mathrm{V}}{\partial\eta^2}+(\rho^2-\mu^2)\frac{\partial^2\mathrm{V}}{\partial\zeta^2}=0,$$

where ξ, η, ζ are defined by the formulae

$$\xi=\int_h^\rho\frac{d\rho}{\sqrt{\rho^2-h^2}\sqrt{\rho^2-k^2}},\ \eta=\int_h^\mu\frac{d\mu}{\sqrt{\mu^2-h^2}\sqrt{k^2-\mu^2}},$$
$$\zeta=\int_0^\nu\frac{d\nu}{\sqrt{h^2-\nu^2}\sqrt{k^2-\nu^2}},$$

which are equivalent to

$$\rho=k\,dn(k\xi,k_1),\ \mu=k\,dn(\mathrm{K}-k\eta,k_1),\ \nu=k\,sn(k\xi,k_1'),$$

where k_1^2, $k_1'^2$ denote the quantities $1-h^2/k^2$, h^2/k^2 and K denotes the complete elliptic integral

$$\int_0^{\frac{1}{2}\pi}\frac{d\psi}{\sqrt{1-k_1^2\sin^2\psi}}$$

It can now be shown that Laplace's equation is satisfied by the product $\mathrm{E}(\rho)\mathrm{E}(\mu)\mathrm{E}(\nu)$, where $\mathrm{E}(\rho)$ satisfies the differential equation

$$\frac{d^2\mathrm{E}(\rho)}{d\xi^2}-\{n(n+1)\rho^2-(h^2+k^2)p\}\mathrm{E}(\rho)=0;$$

and $\mathrm{E}(\mu)$, $\mathrm{E}(\nu)$ satisfy the equations

$$\frac{d^2\mathrm{E}(\mu)}{d\eta^2}+[n(n+1)\mu^2-p(h^2+k^2)]\mathrm{E}(\mu)=0,$$

$$\frac{d^2\mathrm{E}(\nu)}{d\zeta^2}-[n(n+1)\nu^2-p(h^2+k^2)]\mathrm{E}(\nu)=0,$$

where n and p are arbitrary constants. On substituting the values of the parameters ξ, η, ζ in terms of ρ, μ, ν, we find that the equation satisfied by $\mathrm{E}(\rho)$ becomes

$$(\rho^2-h^2)(\rho^2-k^2)\frac{d^2\mathrm{E}(\rho)}{d\rho^2}+\rho(2\rho^2-h^2-k^2)\frac{d\mathrm{E}(\rho)}{d\rho}$$
$$+\{(h^2+k^2)p-n(n+1)\rho^2\}\mathrm{E}(\rho)=0,$$

and $\mathrm{E}(\mu)$, $\mathrm{E}(\nu)$ satisfy equations in μ, ν respectively of identically the same form; this equation is known as Lamé's equation.

If n be taken to be a positive integer, it can be shown that it is possible in $2n+1$ ways so to determine p that the equation in $\mathrm{E}(\rho)$ is satisfied by an algebraical function of degree n, rational in ρ, $\sqrt{(\rho^2-h^2)}$, $\sqrt{(\rho^2-k^2)}$. The functions so determined are called Lamé's functions, and the $2n+1$ functions of degree n are of one of the four forms.

$$\mathrm{K}(\rho)=a_0\rho^n+a_1\rho^{n-2}+\ldots,$$
$$\mathrm{L}(\rho)=\sqrt{\rho^2-h^2}(a_0'\rho^{n-1}+a'_1\rho^{n-3}+\ldots),$$
$$\mathrm{M}(\rho)=\sqrt{\rho^2-k^2}(a_0''\rho^{n-1}+a''_1\rho^{n-3}+\ldots),$$
$$\mathrm{N}(\rho)=\sqrt{\rho^2-k^2}\sqrt{\rho^2-h^2}(a_0'''\rho^{n-2}+a_1'''\rho^{n-4}+\ldots).$$

These are the four classes of Lamé's functions of degree n; of the functions K there are $1+\frac{1}{2}n$, or $\frac{1}{2}(n+1)$, according as n is even or odd; of each of the functions L, M, there are $\frac{1}{2}n$, or $\frac{1}{2}(n-1)$, and of the functions N, there are $\frac{1}{2}n$, or $\frac{1}{2}(n+1)$.

The normal forms of solution of Laplace's equation, applicable to the space inside the ellipsoid, are the $2n+1$ products $\mathrm{E}(\rho)\ \mathrm{E}(\mu)\ \mathrm{E}(\nu)$. It can be shown that the $2n+1$ values of p are real and unequal.

It can be shown that, subject to certain restrictions, a function of μ and ν, arbitrarily given over the surface of the ellipsoid $\rho=\rho_1$, can be expressed as the sum of products of Lamé's functions of μ and ν, in the form

$$\sum_1^\infty\sum_{s=1}^{2n+1}c_n^s\mathrm{E}_n^s(\mu)\mathrm{E}_n^s(\nu);$$

the potential function for the space inside the ellipsoid, which has the arbitrarily given value over the surface of the ellipsoid, is consequently

$$\sum\sum c_n^s\frac{\mathrm{E}_n^s(\rho)\mathrm{E}_n^s(\mu)\mathrm{E}_n(\nu)}{\mathrm{E}_n^s(\rho_1)}.$$

It can be shown that a second solution of Lamé's equation is $\mathrm{F}_n(\rho)$ where

$$\mathrm{F}_n(\rho)=(2n+1)\mathrm{E}_n(\rho)\int_\rho^\infty\frac{d\rho}{\{\mathrm{E}_n(\rho)\}^2\sqrt{\rho^2-h^2}\sqrt{\rho^2-k^2}};$$

this function $\mathrm{F}_n(\rho)$ vanishes at infinity as ρ^{-n-1}, and is therefore adapted to the space outside the bounding ellipsoid. The external potential which has at the surface $\rho=\rho_1$, the value

$$\sum\sum c_n^s\mathrm{E}_n^s(\mu)\mathrm{E}_n^s(\nu)\text{ is }\sum\sum c_n^s\frac{\mathrm{F}_n^s(\rho)}{\mathrm{F}_n^s(\rho_1)}\mathrm{E}_n^s(\mu)\mathrm{E}_n^s(\nu).$$

32. *History and Literature.*—The first investigator in the subject was Legendre, who introduced the functions known by his name, and at present also called zonal surface harmonics; he applied them to the determination of the attractions of solids of revolution. Legendre's investigations are contained in a memoir of the Paris Academy, *Sur l'attraction des sphéroides*, published in 1785, and in a memoir published by the Academy in 1787, *Recherches sur la figure des planètes*; his investigations are collected in his *Exercices*, and in his *Traité des functions elliptiques*. The potential function was introduced by Laplace, who also first obtained the equation which bears his name; he applied spherical surface harmonics to the determination of the potential of a nearly spherical solid, in his memoir, *Théorie des attractions des sphéroides et de la figure des planètes*, published by the Paris Academy in 1785. Laplace was the first to consider the functions of two angles, which functions have consequently been known as Laplace's functions; his investigations on these functions are given in the *Mécanique céleste*, tome ii. livre iii., tome v. livre xi., and in the supplement to vol. v. The notation $\mathrm{P}^{(n)}$ was introduced by Dirichlet (see Crelle's *Journal*, vol. xvii., "sur les séries dont le terme général dépend de deux angles" &c.; see also his memoir, "Ueber einen neuen Ausdruck zur Bestimmung der Dichtigkeit einer unendlich dünnen Kugelschale," in the *Abhandlungen* of the Berlin Academy, 1850). The name "Kugelfunctionen" was introduced by Gauss (see *Collected Works*, vi. 648). A direct investigation of the expression for the reciprocal of the distance between two points in spherical surface harmonics was given by Jacobi (Crelle's *Journal*, vol. xxvi., see also vol. xxxii.). The functions of the second kind were first introduced by Heine (see his "Theorie der Anziehung eines Ellipsoides," Crelle's *Journal*, vol. xlii., 1851). The above-mentioned investigators employed almost entirely polar co-ordinates; the use of Cartesian co-ordinates for the expression of spherical harmonics was introduced by Kelvin in his theory of the equilibrium of an elastic spherical shell (see

Phil. Trans. Roy. Soc., 1862), and also independently by Clebsch (see his paper, "Ueber die Reflexion an einer Kugelfläche," Crelle's *Journal*, vol. lxi., 1863). The general theory of spherical harmonics of unrestricted degree, order and argument has been treated by Hobson (*Phil. Trans.*, 1896); see also a paper by Barnes in the *Quar. Journ. Math.* 39, p. 97. The functions which bear the name of Bessel were first introduced by Fourier in his investigations on the conduction of heat (see his *Théorie analytique de la chaleur*, 1822); they were employed by Bessel in the theory of planetary motion (see the *Abhandlungen* of the Berlin Academy, 1824). The functions which are now known as Bessel's functions of degree half an odd integer were employed by Poisson in the theory of the conduction of heat in a solid spherical body (see the *Journ. de l'école polyt.*, 1823, cah. 19). The toroidal functions were introduced by C. Neumann (*Théorie der Elektricitäts- und Wärmevertheilung in einem Ringe*, Halle, 1864), and independently by Hicks (*Phil. Trans. Roy. Soc.*, 1881). The ellipsoidal harmonics were first investigated by Lamé in connexion with the stationary motion of heat in an ellipsoidal body (see Liouville's *Journal*, 1839, pt. iv. The external ellipsoidal harmonics were introduced by Liouville and Heine (see Liouville's *Journal*, vol. x., and Crelle's *Journal*, vol. xxix.). The ellipsoidal harmonics have been considered as expressed in Cartesian co-ordinates by Green (see *Collected Works*), by Ferrers (see his treatise), and by W. D. Niven (*Phil. Trans. Roy. Soc.*, 1892). A method of representing ellipsoidal harmonics in a form adapted for actual use in certain physical problems has been developed by G. H. Darwin (*Phil. Trans.*, vol. 197).

The following treatises may be consulted: Heine, *Theorie der Kugelfunctionen* (2nd ed., 1878, vol. i.; 1881, vol. ii.); this treatise gives much information as to the history and literature of the subject; Ferrers, *Spherical Harmonics* (Cambridge, 1881); Todhunter, *The Functions of Laplace, Lamé and Bessel* (Cambridge, 1875); Thomson and Tait, *Natural Philosophy* (1879), App. B: Haentzschel, *Reduction der Potentialgleichung auf gewöhnliche Differentialgleichungen* (Berlin, 1893); F. Neumann, *Beiträge zur Theorie der Kugelfunctionen* (Leipzig, 1878); C. Neumann, *Theorie der Bessel'schen Functionen* (Leipzig, 1867); *Ueber die nach Kreis-, Kugel- und Cylinder-functionen fortschreitenden Entwickelungen* (Leipzig, 1881); Lommel, *Studien über die Bessel'schen Functionen* (Leipzig, 1868); Mathieu, *Cours de physique mathématique* (Paris, 1873); Pockels, *Ueber die partielle Differentialgleichung* $\Delta u+k^2u=0$ (Berlin, 1891); Bôcher, *Ueber die Reihenentwickelungen der Potentialtheorie* (Leipzig, 1894); Gray and Mathews, *Treatise on Bessel's Functions*; Dini, *Serie di Fourier e altre rappresentazione* . . . (Pisa, 1880); Graf and Gubler, *Einleitung in die Theorie der Bessel'schen Functionen* (Berne, 1898); Nielsen, *Handbuch der Theorie der Cylinderfunktionen* (Leipzig, 1904); Whittaker, *A Course of Modern Analysis* (Cambridge, 1902); H. Weber, *Die partiellen Differentialgleichungen der Physik* (Bremen, 1900); W. E. Byerly, *Fourier's Series and Spherical, Cylindrical and Ellipsoidal Harmonics* (Boston, 1893). (E. W. H.)

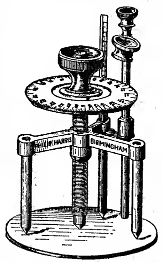
SPHEROID (Gr. σφαῖρα-ειδής, like a sphere), a solid resembling, but not identical with, a sphere in shape. In geometry, the word is confined to the figures generated by an ellipse revolving about a diameter. If the axis of revolution be the major axis of the ellipse, the spheroid is "prolate"; if the minor axis, "oblate"; if any other, "universal."

If the generating ellipse has for its equation $x^2/a^2+y^2/b^2=1$, and revolves about the major axis, *i.e.* the axis of x, the volume of the solid generated is $\frac{4}{3}\pi ab^2$, and its surface is $2\pi\{b^2+(ab/e)\sin^{-1}e\}$, where e denotes the eccentricity. If the curve revolve about the minor axis, the volume is $\frac{4}{3}\pi a^2b$, and the surface is $\pi\{2a^2+(b^2/e)\log(1+e)/(1-e)\}$. The figure of the earth is frequently referred to as an oblate spheroid; this, however, is hardly correct, for the geoid has three unequal axes. The Cartesian equation to a spheroid assumes the forms $x^2/a^2+(y^2+z^2)/b^2=1$, for the prolate, and $(x^2+z^2)/a^2+y^2/b^2=1$, for the oblate, the origin being the centre and the co-ordinate axes the axes of the original ellipse, $x^2/a^2+y^2/b^2=1$, and the line perpendicular to the plane containing them.

In physics, the term "spheroidal state" is given to the following phenomenon. If drops of a liquid be placed on a highly heated surface, for example, the top of a stove, the liquid forms a number of tremulous globules which continually circulate internally. There is no visible boiling, although the globule diminishes slowly in size. The theory of the experiment is that the liquid is surrounded by an elastic envelope of its vapour which acts, as it were, as a cushion preventing actual contact of the drop with the plate. On the formation of a similar protective cushion of vapour depends the immunity of such experiments as plunging a hand into a bath of molten metal.

SPHEROMETER (Gr. σφαῖρα, a sphere, μέτρον, a measure), an instrument for the precise measurement of the radius of a sphere or the thickness of a thin plate. The usual form consists of a fine screw moving in a nut carried on the centre of a small three-legged table; the feet forming the vertices of an equilateral triangle (see figure).

The lower end of the screw and those of the table legs are finely tapered and terminate in hemispheres, so that each rests on a point. If the screw has two turns of the thread to the millimetre the head is usually divided into 500 equal parts, so that differences of 0·001 millimetre may be measured without using a vernier. A lens, however, may be fitted, in order to magnify the scale divisions. A vertical scale fastened to the table indicates the number of whole turns of the screw and serves as an index for reading the divisions on the head. In order to measure the thickness of a plate the instrument is placed on a perfectly level plane surface and the screw turned until the point just touches; the exact instant when it does so is defined by a sudden diminution of resistance succeeded by a considerable increase. The divided head and scale are read; the screw is raised; the thin plate slipped under it; and the process is repeated. The difference between the two readings gives the required thickness. A contact-lever, delicate level or electric contact arrangement may be attached to the spherometer in order to indicate the moment of touching more precisely than is possible by the sense of touch. To measure the radius of a sphere—*e.g.* the curvature of a lens—the spherometer is levelled and read, then placed on the sphere, adjusted until the four points exert equal pressure, and read again. The difference gives the thickness of that portion of the sphere cut off by a plane passing through the three feet. Calling this distance h, and the distance between the feet a, the radius R is given by the formula $R=(a^2+3h^2)/6h$.



SPHERULITES (Gr. σφαῖρα, sphere, λίθος, stone), in petrology small rounded bodies which commonly occur in vitreous igneous rocks. They are often visible in specimens of obsidian, pitchstone and rhyolite as globules about the size of millet seed or rice grain, with a duller lustre than the surrounding glassy base of the rock, and when they are examined with a lens they prove to have a radiate fibrous structure. Under the microscope the spherulites are of circular outline and are composed of thin divergent fibres, which are crystalline and react on polarized light. Between crossed nicols a black cross appears in the spherulite; its axes are usually perpendicular to one another and parallel to the crossed wires; as the stage is rotated the cross remains steady; between the black arms there are four bright sectors. This shows that the spherulite consists of radiate, doubly refracting fibres which have a straight extinction; the arms of the black cross correspond to those fibres which are extinguished. The aggregate is too fine grained for us to determine directly of what minerals it is composed.

Spherulites are commonest in acid glassy rocks like those above mentioned, but they occur also in basic glasses such as tachylyte. Sometimes they compose the whole mass; more usually they are surrounded by a glassy or felsitic base. When obsidians are devitrified the spherulites are often traceable, though they may be more or less completely recrystallized or silicified. In the centre of a spherulite there may be a crystal (*e.g.* quartz or felspar) or sometimes a cavity. Occasionally spherulites have zones of different colours, and while most frequently spherical they may be polygonal, or irregular in outline. In some New Zealand rhyolites the spherulites send branching "cervicorn" processes (like stags' horns) outwards through the surrounding glass of the rock. The name axiolites is given to long, elliptical or band-like spherulites.

Occasionally spherulites are met with which are half an inch or more in diameter. If the rock be pounded up fragments of these can be picked out by hand and subjected to analysis, and it is found that from their composition they may be regarded as a mixture of quartz and acid felspar. Direct microscopic evidence as to the presence of these minerals is rarely obtainable. Some authors describe spherulites as consisting of felsite or microfelsite, which also is supposed to be a cryptocrystalline quartzofelspathic substance.

Very large and cavernous spherulites have been called *lithophysae*; they are found in obsidians at Lipari, the Yellowstone Park, &c. The characteristic radiate fibrous structure is usually conspicuous, but the fibres are interrupted by cavities which are often arranged as to give the spherulite a resemblance to a rosebud with folded petals separated by arching interspaces. Some of these lithophysae are an inch or more in diameter. In the crystallization of a glass there must be contraction, and it is supposed that thus the concentric cavities arise. The steam and other vapours in the magma would fill these empty spaces and exert a powerful mineralizing action on the warm rock. The presence of garnet, tridymite, fayalite and other minerals, very abnormal in rhyolites in these cavities, in the lithophysae is accounted for in this way. The fibres of these coarse spherulites are often broad and seem to belong to alkali felspar (sanidine or anorthoclase) embedded in tridymite and glass; by analogy it is often inferred that the extremely tenuous fibres of ordinary spherulites have the same composition.

Artificial glass which has not the right composition, or is retained for too long a time in a furnace, sometimes crystallizes, and contains spherulites which may be as large as a marble. As the glass has little similarity in chemical composition to volcanic obsidians these spherulites when analysed throw little light on the mineral nature of spherulites in rocks. They show, however that in viscous semi-solid glasses near their fusion point crystallization tends to originate at certain centres and to spread outwards, producing spherulitic structures. Many salts and organic substances exhibit the same tendency, yielding beautiful spherulite crystallizations when melted and cooled rapidly on a microscopic slide.

There are many structures in rocks which are allied to spherulites and usually grouped with them, though probably they are not exactly of the same nature. Some are more vitreous, while others are more perfectly crystalline than the true spherulites. Of the former we mention the doubly refracting glassy spheroids common in rhyolites and obsidians. They differ in no respect from the surrounding hyaline base in ordinary light, but between crossed nicols appear as rounded bodies faintly lighted, with a black cross like that of the spherulites. They are portions of the glass which are in a state of compression or strain and hence no longer isotropic. In gelatin, celluloid and artificial glasses similar appearances are occasionally seen. Opal, especially the variety known as hyalite, exhibits the same phenomenon.

In the group of porphyries known as granophyres crystals of quartz and felspar occur surrounded by a ground-mass which has a radiate fibrous or spherulitic structure. The fibres consist of quartz and felspar, usually in graphic intergrowth over considerable areas, and often sufficiently coarse to be easily distinguishable by means of the microscope. Often the quartz or the felspar of the spherulite extinguishes simultaneously with a crystal of either of these minerals lying in the centre of the aggregate. Exactly what the relationships of the spherulites are to those of the obsidians has never been cleared up; they are probably analogous growths but not identical. The name granospheres has been given to these bodies. Another group of radiate fibrous growths resembling spherulites in many respects consists of minute feathery crystals spreading outwards through a fine grained or glassy rock. In the variolites there are straight or feathery felspar crystals (usually oligoclase) forming pale coloured spherulites, a quarter to half an inch in diameter. The same rocks often contain similar aggregates of plumose skeleton crystals of augite. Many volcanic rocks have small lath-shaped crystals of felspar or augite diverging from a common centre. To distinguish these radiate crystal groups from the cryptocrystalline spherulites they have been called sphaerocrystals. They are commonest in those rocks which contain a fine ground-mass and have been rapidly consolidated. Stellate groupings are frequent also in secondary minerals, being very characteristic of natrolite, chlorite and chalcedony; often the component prisms are very narrow and regularly arranged so that in microscopic sections they give a black cross exactly like that of the spherulites. (J. S. F.)

SPHINX (Gr. σφίγγειν, to draw tight, squeeze), the Greek name for a compound creature with lion's body and human head. The Greek sphinx had wings and female bust, and the male sphinx of Egypt (wingless) is distinguished as "androsphinx" by Herodotus. The type perhaps originated in Egypt, where figures of gods with human bodies and animal heads, and compound animal forms like the gryphon were numerous from very early times. The sphinx, however, is a perfectly clear and well-defined type there, and is usually recumbent. The most celebrated example is the Great Sphinx of Giza, 189 ft. long, a rock carved into this shape, and from its situation likely to be a work of the IVth Dynasty. The pattern of the wig-lappets has been quoted to prove that it dates from the XIIth Dynasty, but it is said that the peculiar disposition of the uraeus on its forehead agrees with that in the earliest sculptures. The face looks out due eastward from the pyramid field over the Nile valley, and, according to the inscriptions of the XVIIIth Dynasty in the shrine between the paws, it represented the sun-god Harmachis. Sphinxes of granite, &c., occur of the XIIth Dynasty and later. A pair from Tanis are attributed by Flinders Petrie to Pepi I. of the VIth Dynasty. The heads of the sphinxes are royal portraits, and apparently they are intended to represent the power of the reigning Pharaoh. The king as a sphinx, in certain religious scenes, makes offerings to deities; and elsewhere he tears his enemies in pieces. In the Saite period accordingly the figure of the sphinx was used as a hieroglyph for *neb*, "master," "lord." Recumbent sphinxes were especially used in pairs to guard the approach to a temple, and it may be conjectured that the Great Sphinx was sculptured at Giza to guard the entrance of the Nile valley. The name of the sphinx in Egyptian was Hu.

The great temple avenues at Thebes are lined with recumbent rams, true sphinxes (a few late instances), and with the so-called criosphinxes or ram-sphinxes, having lion bodies and heads of the sacred animal of Ammon. A falcon-headed sphinx was dedicated to Harmachis in the temple of Abu Simbel, and is occasionally found in sculptures representing the king as Horus, or Mont, the war-god. It is distinguishable from the gryphon only by the absence of wings.

W. M. F. Petrie, *History of Egypt from the Earliest Times to the XVIth Dynasty*, p. 51, &c.; L. Borchardt, "Das Alter der grossen Sphinx," in *Sitzungsberichte* of the Berlin Academy (1897), p. 752. Baedeker's *Egypt*; Prisse d'Avennes, *Histoire de l'art égyptien* (Paris, 1878), vol. ii. pl. 26, 35, text, pp. 405, 410. (F. Ll. G.)

From Egypt the figure of the sphinx passed to Assyria, where it appears with a bearded male head on cylinders; the female sphinx, lying down and furnished with wings, is first found in the palace of Esar-haddon (7th cent. B.C.). Sphinxes have been found in Phoenicia, one at least being winged and another bearded. They are copies of the Egyptian, both in form and posture, wearing the pshent and the uraeus, but distinguished by having the Assyrian wings. The sphinx is common on Persian gems, and the representations are finely executed. On a Persian intaglio are two sphinxes face to face, each wearing a tiara and guarding a sacred plant which is seen between them; but the sphinx, whether of the Egyptian or the Assyrian type, is not found in Persian sculptures (Perrot and Chipiez, *History of Art in Persia*, Eng. trans., London, 1892). In Asia Minor the oldest examples are the "Hittite" sphinxes of Euyuk. They are Egyptian sphinxes treated in the Assyrian style. They are not recumbent, and the hair falling from the head is curled, not straight, as in the true Egyptian sphinx. An ancient female sphinx, but wingless, stands on the sacred road near Miletus. Sphinxes of the usual Greek type are represented seated on each side of two doorways in an ancient frieze found by Sir Charles Fellowes at Xanthus in Lycia, and now in the British Museum. The same type appears on the early sculptures of the half-Greek, half-Oriental temple at Assus. In the early art of Cyprus—the half-way house between Asia and Greece—sphinxes of this type are not uncommon. On the other hand, on a gem of Phoenician style found at Curium in Cyprus there appear two male (bearded) sphinxes, with the tree of life between them. With regard to Greece proper, in the third tomb on the acropolis of Mycenae were found six small golden sphinxes; they are beardless, but the sex is doubtful. The bust is not that of a woman, though the head and face are distinctly feminine. A shallow cap covers the head, and from the middle of it there is always a sort of tail or plume, blown back by the wind. It is curious that, though the sphinx (as also the gryphon) were thus common in the Mycenaean period, the words σφίγξ and γρύψ do not occur in Homer. Helbig suggested that the word κύων (dog), which is connected with the sphinx in the tragedians, was used by Homer for the sphinx, but this theory has not met with general acceptance. In the ancient tomb discovered in 1877 at Spata near Athens (which represents a kindred but somewhat later art than the tombs at Mycenae) were found female winged sphinxes carved in ivory or bone. Sphinxes on glass plates have been found in graves at Camirus in Rhodes and on gold plates in Crimean graves. Sphinxes were represented on the throne of Apollo at Amyclae and on the metopes at Selinus; in the best period of Greek art a sphinx was sculptured on the helmet of the statue of Athena in the Parthenon at Athens; and sphinxes carrying off children were sculptured on the front feet of the throne of Zeus at Olympia. There is also an Athenian vase from Capua in the form of a sphinx painted white. It is winged, and the face is smooth and delicate in contour. Though Greek sphinxes are in general winged, there have been found in Boeotia terra-cotta figures of wingless sphinxes. Roman sphinxes of a late period have sometimes a man's, sometimes a woman's head with an asp on the forehead. An indefinable man-lion (*nara sinha*) represents the fourth *avatar* of the Indian Vishnu, and is found also among the Tibetans.

In Greek mythology the most famous sphinx was that of Thebes in Boeotia, first mentioned by Hesiod (*Theog.* 326), who calls her the daughter of Orthus and Chimaera. According to Apollonius (iii. 5, 8), she was the daughter of Typhon and Echidna, and had the face of a woman, the feet and tail of a lion and the wings of a bird. She dwelt at the south-east corner of Lake Copais on a bald rocky mountain called Phicium (mod. Fagas), which was derived from Φίξ, the Aeolic form of σφίγξ. The Muses taught her a riddle and the Thebans had to guess it. Whenever they failed she carried one of them off and devoured him. The riddle was this: "What is that which is four-footed, three-footed, and two-footed?" At last Oedipus guessed correctly that it was man; for the child crawls on hands and feet, the adult walks upright, and the old man supports his steps with a stick. Then the sphinx threw herself down from the mountain.

The story of the sphinx's riddle first occurs in the Greek tragedians. Milchhöfer believes that the story was a mere invention of Greek fancy, an attempt to interpret the mysterious figure which Greek art had borrowed from the East. On the other hand, he holds that the destroying nature of the sphinx was much older, and he refers to instances in both Egyptian and Greek art where a sphinx is seen seizing and standing upon a man. And, whereas the Theban legend is but sparingly illustrated in Greek art, the figure of the sphinx appears more commonly on tombs, sculptured either in the round or in relief. From this Milchhöfer seems to infer that the sphinx was a symbol of death.

Among the remains of the Mayan culture in Yucatan are found examples of sphinxes, male and female, which are not unlike those of Egypt and Asia Minor.

SPIDER-MONKEY, the English title of a group of tropical American monkeys known to the natives of Brazil by the name coaita, and to zoologists as *Ateles*, in allusion to the imperfectly-developed thumb. They take their English name from the slimness of the body, the elongated limbs, and the long tail, the under surface of the prehensile extremity of which is naked. The thumb is either rudimentary or wanting, so that the hands act merely as hooks in climbing. The absence of woolly under-fur, the less compressed nails, and the broader partition between the nostrils distinguishes them from the woolly spider-monkeys (*Brachyteles.*) The species are numerous, and the most active and thoroughly arboreal of all American monkeys. The prehensile tail is employed not only as a means of suspension, but also to convey food to the mouth. These monkeys generally go about in small parties, high up in the trees; and, like the other members of the group, are comparatively silent. Their food consists chiefly of fruits and leaves. (See PRIMATES.)

SPIDERS, the common English name of Arachnida (*q.v.*) of the order Araneae, resembling the Pedipalpi in many structural points, but differing from them as well as from all other Arachnida in retaining short abdominal appendages known from their silk-manipulating function as spinnerets or spinning mamillae, with which are associated silk glands. It is probably owing to the possession of such glands and the varied purposes for which the silk is used that spiders as a group far surpass the other orders of Arachnida, with the possible exception of the Acari (mites and ticks), in diversity of form and of size, in numbers of genera and species, in extent of geographical distribution, and in adaptation to varied habitats. Except in the extreme north and south, and on the tops of the highest mountains, where there is no insect life as food supply, spiders are found all over the world, even in isolated oceanic islands. They occur up mountain slopes as far as vegetation extends, in tropical valleys and forests, in open grassy plains, in sandy deserts, and even in fresh-water ponds and between tide-marks on the seashore. Some are nocturnal, some diurnal; some catch their prey by speed of foot, some by cunningly lying hid, some by means of silken nets. The phenomena known as "protective resemblance," or similarity to inanimate objects or vegetation, and the kindred phenomenon of "mimicry," or beneficial likeness to certain protected species of animals, are common in the group. In these particulars, considered in their entirety, spiders show a marked contrast to other Arachnida, such as the scorpions, pedipalps, book-scorpions and so-called harvest spiders, which by comparison are remarkably uniform, within the limits of the orders, in structure, habits and other respects. Spiders, in short, must be regarded as the most highly organized and the most successful members of the class Arachnida.

Their success in the struggle for existence, as already indicated, must be assigned in a great measure to the possession of silk glands and to their power of manipulating the silk for a variety of purposes. Several facts point to the conclusion that the primary use of this secretion was the formation of egg-cases or cocoons by the female, for this is the only constant use for which the silk is employed, without exception, by all species. The second step in the evolution of spinning instincts was probably the making of a silken chamber for the reception of the cocoon itself and for the protection of the mother while guarding it and her newly-hatched young. If an aperture for ingress and egress, for purposes of feeding, were left in the wall of such a chamber, there would arise in a rudimentary form what is known as the tubular nest or web; and the next important step was possibly the adoption of such a nest as a permanent abode for the spider. Some spiders, like the *Drassidae* and *Salticidae*, have not advanced beyond this stage in architectural industry; but next to the cocoon this simple tubular retreat—whether spun in a crevice or burrow or simply attached to the lower side of a stone—is the most constant feature to be observed in the spinning habits of spiders. From this starting-point the evolution of web-making seems to have proceeded along two main divergent lines. Along one line there was a gradual elaboration of the tube until it culminated, so far as structural complexity is concerned, in the so-called trap-door nests or burrows of various families; along the other line the tubular retreat either retains its primitive simplicity in association with a new structure, the snare or net, or is entirely superseded by the latter.

Trap-door nests are made by spiders belonging to two widely different groups, namely the *Lycosidae* or wolf-spiders, to which the true tarantula (*q.v.*) belongs, and the Mygalomorphae, containing the species which construct the best-known types of this style of burrow. Although there is no direct genetic affinity between the spiders of these two groups, an interesting parallelism in their habits may be traced. In both there are species which form no nest or burrow, others which construct a simple silk-lined tunnel in the soil, and others which close the aperture of the burrow with a hinged door; while both share the habit of lining the burrow with silk to prevent the infall of loose sand or mould; and the species which make an open burrow close the aperture with a sheet of silk in the winter during hibernation and open it again in the spring. Possibly from this habit was developed the instinct to build a door with a movable hinge. In the trap-door species of *Lycosidae,* like, for instance, *Lycosa opifex* of the Russian steppes, the hinge is weak and the lid of the burrow is kept normally shut by being very much thicker and heavier at its free margin opposite the hinge so that it readily falls by its own weight. In the burrows made by the Mygalomorphae, on the contrary, the hinge is strong and highly elastic, its component silken threads being laid on in such a way that the door shuts with a snap when the occupant has passed in or out. The lid is sometimes thin and wafer-like as in the burrow of the species of *Nemesia,* sometimes thick and cord-like as in that of the species of *Cteniza* or *Pachylomerus.* Its upper side is always covered by the spider with pieces of the vegetation growing hard by, so that, when the door is closed, the position of the burrow is completely concealed. If an attempt be made by any enemy to lift the lid, the spider seizes its inner side with his fangs and striking his claws into the walls of the burrow offers the greatest possible resistance to the efforts of the intruder. When on the watch for prey the spider slightly raises the lid and, peeping through the chink, darts like a flash upon any beetle or fly that unwittingly passes within reach. Quite commonly the burrow has a second passage running obliquely upwards from the main passage to the surface of the soil, and this subsidiary track may itself be shut off from the main branch by an inner door, so that when an enemy has forced an entrance through the main door, the spider retreats behind the second, leaving the intruder to explore the seemingly empty burrow.

There is no doubt that the primary influence that has guided the evolution of the architecture of the burrowing spiders has been that great necessity for the preservation of life, avoidance of enemies and protection from adverse physical conditions like rain, cold or drought. And when we turn to the other line along which the web-building instinct has been developed we find that the primary guiding influence has been that second great vital necessity, namely the necessity of getting food. Reference has already been made to the silken tube or tent, of simple structure, with an orifice at one or both ends, as the possible origin of all snares, however complex they may be. Perhaps the most rudimentary form of snare arose from the spinning of threads round the mouth of the tube to hold it in place. Be that as it may, the snare in many instances, as in that of the *Agalenidae* (*Tegenaria, Agalena*), a family closely allied to the *Lycosidae,* is a horizontal sheet of webbing, upon which the spider runs, continuous with the lower half of the aperture of the tube, of which it is simply an extension. A very similar sheet is spun by a species of *Linyphia,* one of the *Argyopidae,* but in this case there is no tube connected with the web and the spider hangs suspended beneath the horizontal netting. Snares of another type consisting of a tangled mass of threads amongst which the spiders pick their way with ease, but which are impassable to insects, are spun by members of the *Theridiidae* and *Pholcidae*; but by common consent the so-called orbicular web, so characteristic of the *Argyopidae* but by no means confined to them, is regarded as manifesting the greatest perfection of instinct in snare-spinning. These webs, which are typically subcircular in form, consist of a system of threads radiating from a common centre and crossed at intervals, and approximately at right angles, by a series of concentric lines, the whole being suspended in a triangular, quadrangular or polygonal framework formed of so-called foundation lines, attached to the branches or leaves of trees or other firm objects in the neighbourhood. Passing back from the centre of the web to the underside of an adjoining leaf or some other sheltered spot runs a single thread, the trap line affording passage to the spider to and from the sheltered spot and the snare itself. At whatever spot an insect becomes entangled in the frame, the vibration set up by its struggles is transmitted along the nearest radiating thread to the centre and thence up the trap line to the shelter where the occupant lurks awaiting the signal. No sooner is the vibration perceived than the spider descends with all speed to the centre, and by feeling the ends of the radiating lines learns which is ashake and rapidly, without the possibility of mistake, makes its way to the entangled insect. The probable reason for the wall-lines being concentric is that lines passing over the radii as nearly as possible at right angles are the shortest that can be laid on; they therefore use up a smaller quantity of silk and take a shorter time to spin than threads crossing the radii in any other direction; and at the same time they afford them the greatest possible support compatible with delicacy and strength of construction. On account of its delicacy no web is more difficult to see than one of the orbicular type above described. Its whereabouts is thus, to a great extent, concealed both from enemies searching for spiders and from insects suitable for food; and its open meshwork of strong threads makes it much less liable to be beaten down by rain or torn to shreds by winds than if it were a flat sheet of closely woven silk. In constructing, therefore, a snare of radiating and concentric lines, it seems that a spider economizes both time and silk and in addition renders the web as strong and as serviceable and yet as delicate and invisible as possible.

Perfect orbicular webs are made by many genera of *Argyopidae* (*Zilla, Meta, Gasteracantha*), the best-known example being that of the common garden spider of England, *Aranea* or *Epeira diademata*; but these webs are not associated with any tubular retreat except such as are made under an adjoining leaf or in some nook hard by. Some tropical members of the family belonging to the genus *Nephela,* however, spin a web which is intermediate in structure between that of *Aranea* and the complete sheet-like web of *Agalena.* It covers an area of about one-third of a circle and its radiating threads diverge from the mouth of a funnel-shaped tube resembling in every respect the tube of the last-mentioned genus. Again some species of *Dictyna,* belonging to the *Amaurobiidae,* also have a tubular retreat opening on to the surface of a snare in which a crude attempt at a radial and concentric arrangement of the threads is perceptible. The interest of these two types of web lies in the fact that they bridge over the structural gap between the simple sheet-web of *Agalena* and the perfected orb-web of *Aranea.*

Dictyna may be cited as an example of a group of spiders, sometimes called the Cribellata, which have certain spinning glands and appliances not possessed by others. These glands are represented externally by a special plate, the *cribellum,* which lies in front of the ordinary spinning mamillae, and by a comb of short bristles, the *calamistrum,* placed in the penultimate segment of the left of the last pair. By means of the calamistrum the silk secreted by the cribellum is teased into a fine thread which is twisted round the main threads of the web, giving it a very characteristic woolly or flocculent appearance.

There are many other uses to which silk is put, besides those mentioned above. By trailing a thread behind them spiders are able to drop from any height to the ground and to retrace their steps with certainty to a particular spot. The possession of silk-glands has also profoundly influenced the geographical distribution of spiders and has enabled them to cross arms of the sea and establish themselves on isolated oceanic islands which most of the orders of Arachnida are unable to reach. This is effected by the so-called habit of "ballooning" practised by very young spiders, which float through the air, often at great altitudes, in the direction of the prevalent winds. It was formerly supposed that this custom was peculiar to a single species, which was called the "gossamer" spider from the fact that the floating webs, when brought to the earth by rain or intercepted by bushes and trees, coat the foliage or grass with a sheeting of gossamer-like silk; but the habit is now known to be practised by the newly-hatched young of a great variety of species belonging to several distinct families.

As a commercial product spider-silk has been found to be equal, if not superior, to the best silk spun by lepidopterous larvae; but the cannibalistic propensities of spiders, making it impossible to keep more than one in a single receptacle, coupled with the difficulty of getting them to spin freely in a confined space, have hitherto prevented the silk being used on any extensive scale for textile fabrics.

The methods of catching prey adopted by spiders are extremely varied. The nets or snares are highly efficient for this purpose. Amongst the threads, which entangle the wings and legs of intercepted prey, the spiders are perfectly at home and can pounce on the struggling victim at once if it be small and harmless or keep at a respectful distance, checking all efforts at escape, if it be poisonous or strong. If in the latter case the spider be afraid to come to close quarters, various devices for securing it are resorted to. The *Theridiidae* eject on to the insect from their spinning mamillae drops of liquid adhesive silk; the *Argyopidae*, steadying it with the tips of their long front legs, sweep additional strands of silk over it with the legs of the hinder pair; the *Agalenidae*, attaching a long thread to a point hard by, run round and round the victim in circles, gradually winding it up beyond all hope of breaking loose. Two genera of *Argyopidae* (*Hyptiotes* and *Theridiosoma*) construct spring-nets out of their incomplete webs of the orbicular type. To the web is attached a trap-line which when drawn taut holds the snare stretched and tight, and when relaxed loosens the whole structure so that the threads fall together. When an insect strikes the web the spider loosens his hold of the trap-line, thus enveloping the victim in a tangle of threads which would otherwise not come into contact with it. Spiders which spin no snare are dependent for capturing prey for the most part upon their quickness or powers of lying concealed. Many *Thomisidae* lurk amongst the stamens and petals of flowers, which they closely match in colour, waiting to seize the insects which visit the blossoms for nectar. Examples of *Selenops* (*Clubionidae*) lie flat and absolutely still on the bark of trees, to which their coloration assimilates, and spring like a flash of light upon any insect that touches their legs; the *Lycosidae* dart swiftly upon their prey; and the *Salticidae*, which compared with other spiders have keen powers of vision, stealthily stalk it to within leaping distance, then, gathering their legs together, cover the intervening space with a spring and with unerring aim seize it and bury their fangs in its body. One genus of *Thomisidae* (*Phognarachne*), which inhabits the Oriental region, adopts the clever device of spinning on the surface of a leaf a sheet of web resembling the fluid portions of a splash of bird's dung, the more solid central portions being represented by the spider itself, which waits in the middle of the patch to seize the butterflies or other insects that habitually feed on birds' excrement and are attracted to the patch mistaking it for their natural food.

The sexes of spiders are distinct. Except in the case of the water-spider (*Argyroneta*) the males are smaller, sometimes very much smaller, than the females, but have proportionately longer legs and smaller bodies. When adult the males may always be distinguished from the females by the presence of a pair of horny intromittent organs, one of which is lodged in the terminal segment of each palpus or appendage of the second pair. In its simplest form this is a hollow flask-shaped horny piece, consisting of a dilated basal portion and a terminal spiniform portion with an orifice at the apex; but its structure is frequently complicated by accessory processes and outgrowths which aid copulation and serve to protect the delicate point from injury. In the breeding season the male deposits drops of sperm on a sheet of webbing, picks it up in these flasks by means of capillary attraction and carries it about until he falls in with a female. During pairing he thrusts the tip of these organs into the seminal vesicles of the female and the eggs are fertilized as they pass out of the oviduct. Cases of parthenogenetic reproduction, or reproduction without the intervention of the male, have been recorded in the case of two genera (*Filistata* and *Tegenaria*), and may be commoner than is usually supposed. All spiders are oviparous. The number of eggs produced at a time varies enormously according to the species, from about half a dozen, more or less, in some ant-mimicking *Attidae* or jumping spiders to many hundreds in the larger orbicular-webbed spiders of the family *Argyopidae*. The first act of the female after oviposition is to wrap her eggs in a casing of silk commonly called the cocoon. The cocoon varies greatly in size, shape and consistency according to the nature of the spider that makes it. Sometimes, as in *Pholcus*, it is merely a thin network of silk just sufficient to hold the eggs together. More often it consists of a thick felting of silk, either spun in one continuous piece into a globular form, as in the *Aviculariidae*, or composed of two plate-like pieces, an upper and a lower, united at the edges and lenticular in shape, as in some of the *Lycosidae*. Sometimes it is woolly and flocculent, sometimes smooth like parchment, and its shape depends in a large measure upon the habits of the female towards her offspring. As a rule terrestrial spiders guard the cocoon in the permanent burrow, as in the trap-door spiders, or in the silken retreat which acts as a temporary nursery, as in the *Salticidae*. Other species of wandering habits carry the cocoon about with them, sometimes attached to the spinnerets, as in the *Lycosidae*, sometimes tucked under the thorax, as in the large tropical house-spider, *Heteropoda regia*, one of the *Clubionidae*. The females of some snare-spinning species, like the *Pholcidae*, carry it in their jaws; but in the case of the *Argyopidae* the females usually leave the cocoon to its fate as soon as it is constructed, sometimes rolling it in a leaf, sometimes attaching it by a stalk to a branch. It is in this and related families that the greatest diversity in the colour and form of the cocoon is found. In these spiders, too, the newly-hatched young shift for themselves as soon as they emerge from the cocoon; in others that guard the cocoon the young stay for a longer or shorter time under their mother's protection, those of the wandering *Lycosidae* climbing on her back to be carried about with her wherever she goes. There is no metamorphosis during growth such as occurs in some insects, the young being hatched with its full complement of appendages and only differing from its parents in characters of comparatively minor importance. Growth is accompanied by a succession of moults, the spider emerging from its old skins by means of a fracture which extends along the front and sides of the cephalothorax just beneath the edge of the carapace. It is only at the final moult that the sexual organs are mature, the two sexes being alike in the earlier stages of growth. Until maturity is reached the spider has the power to repair lost or damaged limbs. If a limb be lost at an early stage it may be re-grown in perfection; but at later stages it is only imperfectly reproduced and is shorter and thinner than the other limbs. Rapidity of growth and longevity vary greatly according to circumstances and to the species. In northern and temperate latitudes where insects disappear in the winter, species of *Argyopidae* like *Aranea diademata*, live only for a single season. The young emerge from the cocoon in the early spring, grow through the summer, and reach maturity in the early autumn. The sexes then pair and perish soon after the female has constructed her cocoon. Species of other families (*Lycosidae, Clubionidae*) may live for a few seasons, hibernating in the soil or amongst dead leaves; and examples of the larger spiders (*Aviculariidae*) have been kept alive in captivity for several years.

Owing to the smaller size of the male and the greater voracity of the female, the male makes his advances to his mate at the risk of his life and is not infrequently killed and eaten by her either before or after pairing has been effected. Fully aware of the danger, he pays his addresses with extreme caution, frequently waiting for hours in her vicinity before venturing to come to close quarters. Males of the *Argyopidae* hang on the outskirts of the webs of the females and signal their presence to her by jerking the radial threads in a peculiar manner. Other web-spinning spiders (*Tegenaria*) have somewhat similar habits; and the male of the park-web spider (*Atypus*), one of the Mygalomorphae, taps the walls of the tubular web of the female before daring to bite a hole in it and descend into her burrow. Most curious of all is the courtship of the males of some species of *Salticidae*, or jumping spiders, which are decorated with plumes or coloured stripes or iridescent patches. These they display before her, posing and performing extraordinary antics in her presence exactly as cock birds behave towards their hens. Lastly, the males of some species of spiders differ from the females in possessing stridulating organs consisting of horny ridges and spikes and lodged either between the mandible and palpus as in some species allied to *Linyphia*, one of the *Argyopidae*, or between the cephalo-thorax and abdomen as in *Steatoda*, one of the *Theridiidae* and *Cambridgea*, one of the *Agalenidae*. It is believed that the males of these species signal to their females by means of the sound these organs emit. The greatest disparity in size between the sexes is met with in the tropical genus *Nephila*, the females of which are gigantic representatives of the *Argyopidae*. The male, however, is a veritable pigmy beside the female, and during copulation presents the appearance of a parasite attached to her abdomen. It has been suggested that the diminutive size of the male is of great advantage to him during courtship, because he is enabled to move easily thereby to escape from her clutches should she turn upon him with hostile intent.

All spiders possess a pair of poison-glands, one in each of the chelicerae or mandibles and opening by means of a duct at the tip of the fang. The primary function of this poison is to kill the prey upon which they feed, its action being very rapid upon insects. In a great majority of cases, however, it is comparatively innocuous to human beings, despite legends to the contrary that have arisen in connexion with certain species like the tarantula. The bite, however, of any spider, strong enough to pierce the skin, may give rise to a certain amount of local inflammation and pain depending principally upon the amount of poison injected. The bite, for example, of large species of the family *Aviculariidae*, sometimes called Mygales, and sometimes, but erroneously, known as tarantulas, species which have fangs half an inch long and as sharp as needles and a considerable quantity of poison, may be very painful, though seldom serious provided the health of the patient be good. There is one possible exception, however, to the innocuous nature of the poison and this is supplied by the species of the genus *Lathrodectus*, one of the *Theridiidae*. There is no actual proof that this spider is more poisonous than others, but it is a significant fact that its species, inhabiting countries as widely separated as Chile, Madagascar, Australia, New Zealand and South Europe are held in great fear by the indigenous population, and many stories are current of serious or fatal results following their bites. Many of the species of these spiders, moreover, are very conspicuously coloured, being either wholly black or black relieved by fiery red spots, forcibly suggesting that they are warningly coloured. Some of the species of *Aviculariidae* also appear to be warningly coloured with black or black and red, and their coloration is associated with the urticating nature of their bristles, which makes them highly unpalatable to vertebrate foes. So far as is known, however, only the large spiders belonging to this group possess this special means of defence, and in many other species this is accompanied by highly-developed stridulating organs resembling those of rattlesnakes and scorpions in function. Others again, like *Gasteracantha* and *Acrosoma*, belonging to the *Argyopidae*, are armed with sharp and strong abdominal spines, and these spiders are hard-shelled like beetles and are spotted with black on a reddish or yellow ground, their spines shining with steel-blue lustre. The majority of spiders, however, are soft-skinned and succulent, and are tasty morsels for insectivorous reptiles, birds and mammals. Hence as a very general rule the coloration makes for concealment under natural conditions of existence, and the instincts which lead to concealment are very highly developed. As instances of procryptic or celative coloration may be mentioned that of the species of the genus *Dolomedes*, one of the *Lycosidae*, which lives amongst reeds and is marked with a pair of longitudinal yellow lines which harmonize with the upright stalks of the vegetation, and *Lycosa picta*, which lives on the sand, can scarcely be seen on account of its mottled pattern: *Sparassus smargdulus* and the species of *Pecucetia*, which are found amongst grass or low green herbage, are mostly green in colour, and *Salticus scenicus* is banded with white and black to match the grey tint of the rocks and stone walls on which it hunts its prey. Similar instances of protective coloration could be cited without end. Sometimes the shape of the spider combines with the colour to produce the same effect, as in the species of *Uloborus*, which as they hang in thin shabby-looking webs exactly resemble fragments of wind-blown rubbish. The success of procryptic coloration depends, however, very largely upon stillness, and the instinct to keep stationary without moving a limb is a marked characteristic of all spiders unless engaged in hunting or fleeing from imminent danger. The instinct reaches its highest development in the phenomenon miscalled "death feigning." Spiders of various families will, when alarmed, lie absolutely still with legs tucked up and allow themselves to be pushed and rolled, and handled in various ways without betraying that they are alive by the slightest movement. But it would be absurd to suppose that they are in reality pretending to be dead, because there is no reason to think they can have any knowledge of death. They are merely practising the inherited instinct to lie motionless, movement being the only indication of the presence of living prey known to many insectivorous animals. When concealment is no longer possible terrestrial species, like the *Lycosidae*, dart swiftly to the nearest shelter afforded by crevices in the soil, stones, fallen leaves or logs of wood, while those that live in bushes, like the *Argyopidae*, drop straight to the ground and lie hidden in the earth or in the fallen vegetation beneath.

The extent to which procryptic coloration and instincts favouring concealment are developed indicates that generation after generation spiders have been subjected to persecution from enemies. No doubt large numbers are devoured by insectivorous birds, mammals and reptiles, but the mortality due to them and other foes sinks into insignificance beside that caused by the persecution of hymenopterous insects of the families *Ichneumonidae* and *Pompilidae*, especially of the latter, many species of which systematically ransack the country for spiders wherewith to feed their young in the breeding season. It is no exaggeration to say that countless thousands of spiders of all families are annually destroyed by these insects, and there is no reason to doubt that destruction on at least as great a scale has been going on for centuries, too many even to guess at. Hence it is probable that no factor has had a greater influence than these wasps in moulding the protective instincts and habits of spiders. One interesting phenomenon in spider-life seems to be directly and certainly traceable to this influence, and that is mimicry of ants. In several families of spiders, but principally in those like the *Clubionidae* and *Salticidae*, which are terrestrial in habits, there are species which not only live amongst ants, but so closely resemble them in their shape, size, colour and actions that it requires a practised eye to distinguish the Arachnid from the insect. Now the *Pompilidae* or mason wasps provision their cells with insects of many different kinds, as well as with spiders; but, of the hundreds of species of these wasps that have been described from different parts of the world, only one is known to use ants for this purpose; and this species is not one that preys upon spiders. On the other hand it has been specially recorded of two of the species of spider-destroyers that they have great dislike and apparent fear of these little poisonous Hymenoptera. So, too, does it appear that ants are entirely immune to the attacks of *Ichneumonidae*, which destroy hosts of other insects and of spiders by laying their eggs upon their bodies. But since ants are not persecuted by these two families of Hymenoptera, the greatest enemies spiders have to contend with, it is evident that mimicry of ants is of supreme advantage to spiders. Ants, however, are not the only animals mimicked by spiders. Some members of the *Argyopidae* (*Cyclosa*) are exactly like small snails; others (*Cyrtarachne*) resemble *Coccinellidae* in shape and colour. Now, *Coccinellidae* (ladybirds) are known to be highly distasteful to most insectivorous mammals and birds, and snails would be quite unfit food for the Pompilid or Ichneumonid larvae, so that the reason for the mimicry in these cases is also perfectly clear. The exact extent, however, to which each particular class of enemy has affected the protective habits and attributes of spiders is by no means always evident; and it is impossible to discuss the question in detail within the limits of a short article. But two instances of extreme deviation from the ordinary mode of life due, apparently, like ant-mimicry, solely, if not wholly, to the persecution of Hymenoptera, may be cited as illustrations of the profound effect upon habit brought about by long-continued persecution from enemies of this kind.

This deviation is the adoption of an aquatic mode of life by the European fresh-water spider (*Argyroneta*) and by the marine spider *Desis*, which is found on the shores of the Indian and Pacific Oceans from Cape Colony to eastern Australia. *Desis* lives invariably between tide-marks upon the rocks and coral reefs, and may be found at low tide either crawling about upon them or swimming in tidal pools and feeding upon small fish or crustaceans. As the tide rises the spiders take refuge in crevices and spin over their retreat a sheet of silk, impervious to water, beneath which they lie in safety with a supply of air until the ebb exposes the site again to the sun. The fresh-water spider (*Argyroneta*) lives amongst the weeds of lakes and ponds and, like *Desis*, is quite at home beneath the water either swimming from spot to spot or crawling amongst the stems of aquatic plants. As a permanent home the spider makes beneath the surface a thimble-shaped web, with inverted mouth, anchoring it to the weeds. He then ascends to the surface, carries down a bubble of air and releases it inside the mouth of the silk-thimble, thus replacing a certain amount of water. This action is repeated until the domicile is filled with air, when the spider takes possession of it. The spider owes its name *Argyroneta* or the silver swimmer to its silvery appearance as it swims about under water enveloped in air, and its power to retain an envelope of air on its sternum and abdomen depends upon the circumstance that these areas are beset with hairs which prevent the water reaching the integument; but the air retained by these hairs can be released when the spider wishes to fill its subaqueous home with that element. *Argyroneta* feeds principally upon flies or gnats, which it seizes from below as they light upon the surface of the water. In the breeding season the male spins a bell or thimble near that of the female and joins the two by means of a silken passage. The female attaches her eggs to the inner wall of her own home, and the young when large enough to shift for themselves have the bell-making instinct fully developed. Since the adoption of an aquatic mode of life by *Desis* and *Argyroneta* involves no increased facilities in getting food, and merely substitutes for ordinary terrestrial enemies fishes and crustaceans in the former case, and fishes, amphibians, and insectivorous water-insects in the latter, the supposition is justified that the change in environment is due to the unremitting persecution of *Pompilidae* and *Ichneumonidae*, which would not venture to pursue their prey beneath the water's surface. The habits of certain other spiders suggest the origin of the perfect adaptation to aquatic conditions exhibited by *Desis* and *Argyroneta*. The nature of the integument and its hairy clothing in all spiders enables them to be plunged under water and withdrawn perfectly dry, and many species, even as large as the common English house-spider (*Tegenaria*), are so lightly built that they can run with speed over the surface of standing water, and this faculty has been perfected in genera like *Pirata*, *Dolomedes* and *Triclaria*, which are always found in the vicinity of lakes or on the edges of rivers and streams, readily taking to the water or running down the stems of water plants beneath its surface when pursued. Some species of *Dolomedes*, indeed, habitually construct a raft by spinning dead leaves together and float over the water upon it watching for an opportunity to dash upon any insect that alights upon its surface.

Geologically, spiders date from the Carboniferous Period, *Arthrolycosa* and others from the coal beds of Europe and North America being closely allied to the existing genus *Liphistius*. Remains of spiders from the Baltic amber beds of Oligocene age and from nearly coeval fluviatile or lacustrine deposits of North America belong to forms identical with or closely related to existing genera, thus proving the great antiquity of our present spider fauna. (R. I. P.)

SPIELHAGEN, FRIEDRICH VON (1829–), German novelist, was born at Magdeburg on the 24th of February 1829. He was brought up at Stralsund, where his father was in 1835 appointed government architect; he attended the gymnasium there, and studied law, and subsequently literature and philosophy, at the universities of Berlin, Bonn and Greifswald. On leaving the university he became a master in a gymnasium at Leipzig, but upon his father's death in 1854 devoted himself entirely to writing. After publishing *Klara Vere* (1857) and *Auf der Düne* (1858), he obtained a striking success with *Problematische Naturen* (1860–1861), one of the best novels of its time; it was followed by *Die von Hohenstein* (1863), *In Reih' und Glied* (1866), *Hammer und Amboss* (1869), *Deutsche Pioniere* (1870), *Allzeit voran!* (1872), *Sturmflut* (1876), *Plattland* (1878), *Quisisana* (1880), *Angela* (1881), *Uhlenhans* (1884), *Ein neuer Pharao* (1889), *Faustulus* (1897) and *Freigeboren* (1900). Spielhagen's best work was produced between the years 1860 and 1876; he wrote nothing after *Sturmflut* which can be compared with that powerful romance. His novels combine two elements of especial power, the masculine assertion of liberty which renders him the favourite of the intelligent and progressive citizen, and the ruthless war he wages against the self-indulgence of the age. His love of the sea, derived from an early residence at Stralsund, introduces an element of poetry into his novels which is somewhat rare in German fiction. Spielhagen's dramatic productions, *Hans und Grete* (1868) and *Liebe für Liebe* (1875), and others, cannot compare with his novels. From 1878–1884 he was editor of *Westermann's Monatshefte*.

Spielhagen's *Sämtliche Werke* were published in 1871 in sixteen volumes, in 1878 in fourteen volumes; his *Sämtliche Romane* in 1898 (22 vols.), and these were followed by a new series in 1902. See his autobiography, *Finder und Erfinder* (2 vols., 1890); also G. Karpeles, *F. Spielhagen* (1889), and H. and J. Hart, *Kritische Waffengänge* (1886).

SPIESS, CHRISTIAN HEINRICH (1755–1799), German writer of romances, was born at Freiberg in Saxony on the 4th of April 1755. For a time an actor, he was appointed in 1788 controller on the estate of a certain Count Künigl at Betzdikau in Bohemia, where he died, almost insane, the result of his weird fancies, on the 17th of August 1799.

Spiess, in his *Ritter-, Räuber- und Geister-Romane*, as they are called—stories of knights, robbers and ghosts of the "dark" ages—the idea of which he borrowed from Goethe's *Götz von Berlichingen* and Schiller's *Räuber* and *Geisterseher*, was the founder of the German *Schauerroman* (shocker), a style of writing continued, though in a finer vein, by Karl Gottlob Cramer (1758–1817) and by Goethe's brother-in-law, Christian August Vulpius. These stories, though appealing largely to the vulgar taste, made Spiess one of the most widely read authors of his day. The most popular was a ghost story of the 13th century, *Das Petermännchen* (1793); among others were *Der alte Überall und Nirgends* (1792); *Die Löwenritter* (1794), and *Hans Heiling, vierter und letzter Regent der Erd- Luft- Feuer- und Wasser-Geister* (1798). Beside numerous comedies, Spiess wrote, anticipating Schiller, a tragedy *Maria Stuart* (1784), which was in the same year performed at the court theatre in Vienna.

See Karl Goedeke, *Grundriss*, v. 506 sqq.; Müller-Fraureuth, *Die Ritter- und Räuberromane* (Halle, 1894).

SPIKENARD, or NARD (O. Fr. *spiquenard*, Lat. *spica nardi*, from *spica*, ear of corn, and Gr. *νάρδος*, Pers. *nard*, Skt. *nalada*, Indian spikenard, from Skt, *nal*, to smell), a celebrated perfume which seems to have formed one of the most durable aromatic ingredients in the costly unguents used by the Romans and Eastern nations. The ointment prepared from it ("ointment of pistic nard"[1]) is mentioned in the New Testament (Mark xiv. 3–5; John xii. 3–5) as being "very costly," a pound of it being valued at more than 300 denarii (over £10). This appears to represent the prices then current for the best quality of nard, since Pliny (*H.N.* xii. 26) mentions that nard spikes reached as much as 100 denarii per ℔, and, although he does not mention the price of nard ointment, he states (xiii. 2) that the "unguentum cinnamominum," a similar preparation, ranged from 25 to 300 denarii according to its quality. Nard ointment also varied considerably in price from its liability to sophistication (Ibid. xii. 26, 27; xiii. 2). The genuine ointment[2]

[1] The meaning of the word "pistic" is uncertain, some rendering it "genuine," others "liquid," and others taking it for a local name

[2] The use of alabaster vessels for preserving these fragrant unguents was customary at a very early period. Theophrastus (*c.* 314 B.C.) states that vessels of lead and alabaster were best for the purpose, on account of their density and coolness, and their power

(*unguentum nardinum sive folialum*) contained costus (the root of *Saussurea lappa*), amomum (the fruits of *Amomum cardamomum*), balm (the oleoresin of *Balsamodendron opobalsamum*) and myrrh, with Indian nard (Ibid. xiii. 2).

The exact botanical source of the true or Indian nard was long a matter of uncertainty, the descriptions given by ancient authors being somewhat vague, but it is now identified as *Nardostachys jatamansi*, a plant of the valerian order, the fibrous root-stocks or "spikes" of which are still collected in the mountains of Bhotan and Nepal. The name "spike" is applied apparently from its resemblance in shape to a spike or ear of bearded corn. The root is crowned by the bases of several stems, each about 2 in. or more in length and as thick as the finger. To these the fibrous tissue of former leaves adheres and gives them a peculiar bristly appearance. It is this portion that is chiefly collected.

Other and inferior varieties of nard are mentioned by Dioscorides and subsequent writers. Celtic nard, obtained from the Ligurian Alps and Istria, consisted of the roots of plants also belonging to the valerian order (*Valeriana celtica* and *V. saxatilis*). This was exported to the East and thence to Egypt, and was used in the preparation of baths. Mountain nard was collected in Cilicia and Syria, and is supposed to have consisted of the root of *Valeriana tuberosa*. The false nard of Dauphiné, used in later times, and still employed as a charm in Switzerland, is the root-stock of *Allium victorialis*. It presents a singular resemblance to the spikes of Indian nard, but is devoid of fragrance. It is remarkable that all the nards belong to the natural order *Valerianaceae*, the odour of valerian being considered disagreeable at the present day; that of *Nardostachys jatamansi* is intermediate between valerian and patchouli, although more agreeable than either.

The name "spikenard" has also been applied in later times to several plants. The spikenard of the United States is *Aralia racemosa*, and another species of the same genus, *A. nudicaulis*, or wild sarsaparilla, is known as "wild spikenard." In the West Indies *Hyptis suaveolens* is called "spikenard," and in Great Britain the name "ploughman's spikenard" is given to *Inula conuza*.

SPILLIKINS (M.D., *spelleken*, little pin), or JACKSTRAWS (originally "jerk-straws"), a game of some antiquity played with a set of slender sticks of wood, bone or ivory, from 3 to 6 in. long, generally carved to represent weapons and utensils of various kinds, which are thrown in a heap haphazard upon the table. The players then endeavour in turn to extricate from the heap, one at a time, as many straws as possible, without moving any except the one angled for. The player obtaining the most straws wins. The game is called in French *jonchets* and in German *Federspiel*.

SPINA (Lat. for a thorn, or prickle, also backbone, whence spine), in architecture, the term given to the low podium wall which divided the circus of the Romans and round which the chariots ran; at each end of it was the *meta* or goal. On coins, gems and bas-reliefs it is shown with numerous other features on it, such as obelisks (of which those from the spina of the Circus Maximus are now in the piazzas of the Lateran and del Popolo), small aedicula or pairs of columns carrying an entablature, altars, statues, trophies, &c.

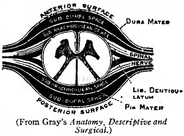
SPINACH (*Spinacia oleracea*), an annual plant, a member of the natural order *Chenopodiaceae*, which has been long cultivated for the sake of its succulent leaves. It is probably of Persian origin, being introduced into Europe about the 15th century. It should be grown on good ground, well worked and well manured; and for the summer crops abundant watering will be necessary.

The first sowing of winter spinach should be made early in August, and another towards the end of that month, in some sheltered but not shaded situation, in rows 18 in. apart—the plants, as they advance, being thinned, and the ground hoed. By the beginning of winter the outer leaves will have become fit for use, and if the weather is mild successive gatherings may be obtained up to the beginning of May. The prickly-seeded and the Flanders are the best for winter; and these should be thinned out early in the autumn to about 2 in. apart, and later on to 6 in. The lettuce-leaved is a good succulent winter sort, but not quite so hardy. To afford a succession of summer spinach, the seeds should be sown about the middle of February, and again in March; after this period small quantities should be sown once a fortnight, as summer spinach lasts but a very short time. They are generally sown in shallow drills, between the lines of peas. If a plot of ground has to be wholly occupied, the rows should be about 1 ft. apart. The round-seeded is the best sort for summer use.

The *Orach* or *Mountain Spinach* (*Atriplex hortensis*), a member of the same order, is a tall-growing hardy annual, whose leaves, though coarsely flavoured, are used as a substitute for spinach, and to correct the acidity of sorrel. The white and the green are the most desirable varieties. The plant should be grown quickly in rich soil. It may be sown in rows 2 ft. apart, and about the same distance in the row, about March, and for succession again in June. If needful, water must be freely given, so as to maintain a rapid growth.

The *New Zealand Spinach* (*Tetragonia expansar*), natural order *Ficoideae*, is a half-hardy annual, native of New Zealand, sometimes used as a substitute for spinach during the summer months, but in every way inferior to it. The seeds should be sown in March, on a gentle hot-bed, having been previously steeped in water for several hours. The seedlings should be potted, and placed under a frame till the end of May, and should then be planted out in light rich soil. The young leaves are those which are gathered for use, a succession being produced during summer and autumn.

SPINAL CORD, in anatomy, that part of the central nervous system in man which lies in the spinal canal formed by the vertebrae, and reaches from the foramen magnum to the lower margin of the first lumbar vertebra. It is about 18 in. long, and only occupies the upper two-thirds of the spinal canal. The cord is protected by the same three membranes which surround the brain. Outside is the *dura mater*, which differs from that of the brain in not forming a periosteum to the bones, in sending no processes inward, and in having no blood sinuses enclosed within its walls. In other words the spinal dura mater is the continuation of only the inner or cerebral layer of the dura mater of the skull. Inside the dura mater is the *arachnoid*, which is delicate and transparent, while between the two lies the *sub-dural space*, which reaches down to the second or third sacral vertebra. The *pia mater* is the innermost covering, and is closely applied to the surface of the cord into the substance of which it sends processes. Between it and the arachnoid is the *sub-arachnoid space*, which is much larger than the sub-dural and contains the cerebro-spinal fluid. Across this space, on each side of the cord, run a series of processes of the pia mater arranged like the teeth of a saw; by their apices they are attached to the dura mater, while their bases are continuous with the pia mater surrounding the cord. These ligaments, each consisting of twenty-one teeth, are the *ligamenta denticulata*, and by them the spinal cord is moored in the middle of the cerebro-spinal fluid.



(From Gray's *Anatomy, Descriptive and Surgical.*)

FIG. 1.—Transverse Section of the Spinal Cord and its Membranes.

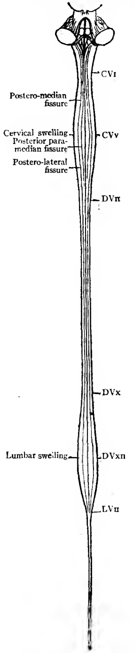
The spinal cord itself is a cylinder slightly flattened from before backward. In the cervical region it is enlarged where the nerves forming the *brachial plexus* come off, while opposite the lower thoracic vertebrae the lumbar enlargement marks the region whence the lumbo-sacral nerves are derived. (See fig. 2.) Opposite the second lumbar vertebra the cylindrical cord becomes pointed and forms the *conus medullaris*, from the apex of which a glistening membranous thread runs down among the nerves which form the *cauda equina*, and, after blending with the termination of the dural sheath, is attached to the back of the coccyx.

In a transverse section of the cord two median fissures are seen; the antero-median (see fig. 3, A) is wide, and reaches about a third of the way along the antero-posterior diameter of the cord; it is lined by the pia mater, which, at its orifice, is thickened to form a

of resisting the penetration of the ointment into their substance. Pliny also recommends alabaster for ointment vases. For small quantities onyx vessels seem to have been used (Horace. *Carm.* iv. 12, lines 10, 17).

glistening band, known as the *linea splendens*; in front of this lies the single anterior spinal artery.

The postero-median fissure (fig. 3, P.) is much deeper and narrower, and has no reflection of the pia mater into it. Where the posterior nerve roots emerge (fig. 3, P.R.) is a depression which is called the *postero-lateral fissure*, while between this and the postero-median a slight groove is seen in the cervical region, the para-median fissure (fig. 3, P.M ; see also fig. 2). On looking at fig. 3 it will be seen that the anterior nerve roots (A.R.) do not emerge from a definite fissure.



(From D. J. Cunningham, in Cunningham's *Text-Book of Anatomy*.)

FIG. 2.—Diagram of the Spinal Cord as seen from behind.

CVI shows the level of the 1st cervical vertebra; CVV of the 5th cervical vertebra; DVII of the 2nd dorsal vertebra; DVX of the 10th dorsal vertebra; DVXII of the 12th dorsal vertebra; LVII of the 2nd lumbar vertebra.

The spinal cord, like the brain, consists of grey and white matter, but, as there is here no representative of the cortical grey matter of the brain, the white matter entirely surrounds the grey. In section the grey matter has the form of an H, the cross bar forming the grey *commissure*. In the middle of this the *central canal* can just be made out by the naked eye (see fig. 4). The anterior limbs of the H form the *anterior cornua*, while the posterior, which in the greater part of the cord are longer and thinner, are the *posterior cornua*. At the tips of these is a lighter-coloured cap (fig. 3, S.G.) which is known as the *substantia gelatinosa Rolandi*. On each side of the H is a slighter projection, the *lateral cornu*, which is best marked in the thoracic region (see fig. 4).

On referring to fig. 4 it will be seen that the grey matter has different and characteristic appearances in different regions of the cord, and it will be noticed that in the cervical and lumbar enlargements, where the nerve to the limbs comes off, the anterior horns are broadened.

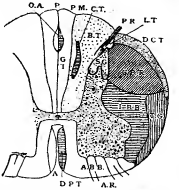


FIG. 3.—Diagram to show the Tracts in the Spinal Cord.

A.	Antero-median fissure.
P.	Postero-median fissure.
A.R.	Anterior nerve roots.
P.R.	Posterior nerve roots.
P.M.	Paramedian fissure.
S.G.	Substantia gelatinosa.
G.T.	Tract of Goll.
B.T.	Tract of Burdach.
C.T.	Comma tract.
O.A.	Oval area.
L.T.	Lissauer's tract.
D.C.T.	Direct cerebellar tract.
T.G.	Gowers' tract.
C.P.T.	Crossed pyramidal tract.
L.B.B.	Lateral basis bundle.
A.B.B.	Anterior basis bundle.
D.P.T.	Direct pyramidal tract.

Histologically the grey matter is made up of neuroglia, medullated and non-medullated nerve fibres, and nerve cells (for details see NERVOUS SYSTEM). The nerve cells are arranged in three main columns, ventral, intermedio-lateral and posterior vesicular. The *ventral cell column* has the longest cells, and these are again subdivided into antero-mesial, antero lateral, postero-lateral and central groups. The *intermedio lateral cell column* is found in the lateral horn of the thoracic region.

The *posterior vesicular* or *Clarke's column* is also largely confined to the thoracic region, and lies in the mesial part of the posterior cornu. It is the place to which the sensory fibres of the sympathetic system (visceral afferents) run. The white matter, as has been shown, surrounds the grey and passes across the middle line to form the *white commissure*, which lies in front of the grey. It is composed of neuroglia and medullated nerve fibres, which are arranged in definite tracts, although in a section of a healthy cord these tracts cannot be distinguished even with the microscope. They have been and are still being gradually mapped out by pathologists, physiologists and embryologists.

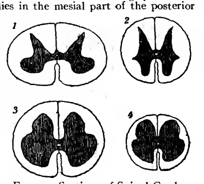

FIG. 4.—Sections of Spinal Cord, twice scale of nature.
1. Cervical enlargement.
2. Thoracic region.
3. Lumbar enlargement.
4. Sacral region.

On tracing a sensory nerve into the cord (fig. 3, P.R.) through the posterior nerve root it will be seen to lie quite close to the mesial side of the posterior horn of grey matter, where most of it runs upward. The next root higher up takes the same position and pushes the former one toward the middle line, so that the lower nerve fibres occupy an area close to the postero-median fissure known as the *tract of Goll* (fig. 3, G.T.), while the higher lie more externally in the *tract of Burdach* (B.T.). The greater part of each nerve sooner or later enters the grey matter and comes into close relation with the cells of Clarke's column, but some fibres run right up to the nucleus gracilis and cuneatus in the medulla (see BRAIN), while a few turn down and form a descending tract, which, in the upper part of the cord, is situated in the inner part of the tract of Burdach and is known as the *comma tract* (fig. 3, C.T.), but lower down gradually shifts quite close to the postero-median fissure and forms the oval area of Flechsig (fig. 3, O.A.). It will be obvious that both these tracts could not be seen in the same section, and that fig. 3 is only a diagrammatic outline of their position.

A few fibres of each sensory nerve ascend in a small area known as *Lissauer's tract* (fig. 3, L.T.) on the outer side of the posterior nerve roots, and eventually enter the substantia gelatinosa.

To the outer side of Lissauer's tract and lying close to the lateral surface of the cord is the *direct cerebellar tract* (fig. 3, D.C.T.), the fibres of which ascend from the cells of Clarke's column to the cerebellum. As Clarke's column is only well developed in the thoracic region this tract obviously cannot go much lower.

In front of the last and also close to the lateral surface of the cord is another ascending tract, the *tract of Gowers* (fig. 3, T.G.), or, as it is sometimes called, the lateral sensory fasciculus. It probably begins in the cells of the posterior horn, and runs up to join the fillet and also to reach the cerebellum through the superior cerebellar peduncle. The *crossed pyramidal tract* (fig. 3, C.P.T.) lies internal to the direct cerebellar tract, between it and the posterior cornu. It is the great motor tract by which the fibres coming from the Rolandic area of the cerebral cortex are brought into touch with the motor cells in the anterior cornu of the opposite side. This tract extends right down to the fourth sacral nerve.

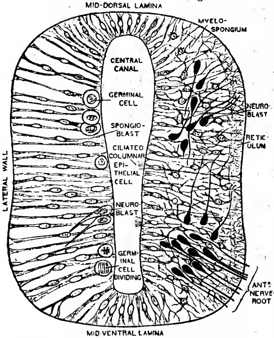
In front of the crossed pyramidal tract is the lateral basis bundle (fig. 3, L.B.B), which probably consists of association fibres linking up different segments of the cord.

The *anterior basis bundle* (fig. 3, A.B.B.) lies in front and on the mesial side of the anterior cornu, and through it pass the anterior nerve roots. Like the lateral bundle it consists chiefly of association fibres, but it is continued up into the medulla as the posterior longitudinal bundle to the optic nuclei.

The *direct pyramidal tract* (fig. 3, D.P.T.) is a small bundle of the motor fibres from the Rolandic area, which, instead of crossing to the other side at the decussation of the pyramids in the medulla, runs down by the side of the antero-median fissure. Its fibres, however, keep on gradually crossing to the opposite side through the anterior white commissure of the cord, and by the time the mid-thoracic region is reached it has usually disappeared.

The roots of the spinal nerves in the upper part of the canal rise from the cord nearly opposite the points at which they emerge between the vertebrae, but the farther one passes down the higher the origin of each root becomes above its point of emergence. Consequently the lumbar and sacral nerves run a long way down from the lumbar enlargement to their spinal foramina and are enclosed in the dural and arachnoid sheaths to form a mass like a horse's tail, which is therefore known as the *cauda equina*. The relation between the origin of each nerve and the spinous processes of the vertebrae has been worked out by R. W. Reid (*Journ. Anat. and Phys.*, xxiii. 341).

Embryology.—The early development of the neural tube from the ectoderm is outlined in the article on the BRAIN. When the neural groove becomes a tube it is oval in section with a very large laterally compressed central canal (see fig. 5). The original ectodermal cells elongate and, radiating outward from the canal, are now known as spongioblasts, while the inner ends of some of them bear cilia and so the canal becomes ciliated. A number of round cells, known as germinal cells, now appear close to the central canal, except at the thin mid-dorsal and mid-ventral laminae (roof-plate and floor-plate). From the division of these the primitive nerve cells or neuroblasts are formed and these later on migrate from the region



(From D. J. Cunningham in Cunningham's *Text-Book of Anatomy.*)

FIG. 5.—Schema of a Transverse Section through the Early Neural Tube (Young).

The left side of the section shows an earlier stage than the right side.

of the canal and shoot out long processes—the axons. The permanent central canal of the cord was formerly said only to represent the ventral end of the large embryonic canal, the dorsal part being converted into a slit by the gradual closing in of its lateral walls, thus forming the postero-median fissure. A. Robinson, however, does not believe that the posterior fissure is any remnant of the central canal, and there are many points which bear out his contention (*Studies in Anatomy*, Owens College, 1891). The most modern view (1908) is that the fissure is formed partly by an infolding and partly from the original central canal. The antero-median fissure is caused by the ventral part of the cord growing on each side, but not in the mid-line where no germinal cells are.

The anterior nerve roots are formed by the axons of the neuroblasts in the developing anterior cornua, but the posterior grow into the cord from the posterior root ganglia (see NERVE: *Spinal*), and, as they grow, form the columns of Goll and Burdach. That part of the grey matter from which the ventral, anterior or motor nerve roots rise is known as the basal lamina of the cord, while the more dorsal part into which the posterior nerve roots enter is the *alar lamina*. These parts are important in comparing the morphology of the spinal cord with that of the brain.

In the embryo up to the fifth month there is little difference in the appearance of the grey and white matter of the cord, but at that time the fibres in the columns of Burdach acquire their medullary sheaths or white substance of Schwann, the fatty matter of which is probably abstracted from the blood. Very soon after these the basis bundles myelenate and then, in the sixth month, the columns of Goll. Next follow the direct cerebellar tracts and, in the latter half of the eighth month the tracts of Gowers, while the fibres of the pyramidal and Lissauer's tracts do not gain their medullary sheaths until just before or after birth. At first the spinal cord exends as far as the last mesodermal somite, but neuroblasts are only formed as far as the first coccygeal somite, so that behind that the cord is non-nervous and degenerates later into the filum terminale. After the fourth month the nervous portion grows more slowly than the rest of the body and so the long cauda equina and filum terminale are produced. At birth the lower limit of the cord is opposite the third lumbar vertebra, but in post-natal development it recedes still farther to the lower level of the first.

For further details see Quain's *Anatomy*, vol. i. (London, 1908); J. P. McMurrich, *Development of the Human Body* (1906). Most modern descriptions are founded on the writings of W. His, references to which and to other literature will be found on p. 463 of McMurrich's book.

Comparative Anatomy.—In the Amphioxus there is little difference between the spinal cord and the brain; the former reaches the whole length of the body and is of uniform calibre. It encloses a central canal from which a dorsal fissure extends to the surface of the cord and it is composed of nerve fibres and nerve cells; most of the latter being grouped round the central canal or neurocoele, as they are in the human embryo. Some very large multipolar ganglion cells are present, and there are also large fibres known as *giant fibres*, the function of which is not clear.

When the reptiles are reached the cord shows slight enlargements in the regions of the limbs and these become more marked in birds and mammals.

In the lumbar region of birds the dorsal columns diverge and open up the central canal, converting it into a diamond-shaped space which is only roofed over by the membranes of the cord, and is known as the *sinus rhomboidalis*.

In all these lower vertebrates except the Anura (frogs and toads), the cord fills the whole length of the spinal canal, but in the higher mammals (Primates, Chiroptera and Insectivora) it grows less rapidly, and so the posterior part of the canal contains the cauda equina within its sheath of dura mater. In mammals below the anthropoid apes there are no direct pyramidal tracts in the cord, since the decussation of the pyramids in the medulla is complete. Moreover, the crossed tracts vary very much in their proportional size to the rest of the cord in different animals. In man, for example, they form 11·87 % of the total cross area of the cord, in the cat 7·76 %, in the rabbit 5·3 %, in the guinea-pig 3 %, and in the mouse 1·14 %. In the frog no pyramidal tract is found. It is obvious, therefore, that in the lower vertebrates the motor fibres of the cord are not so completely gathered into definite tracts as they are in man.

A good deal of interest has lately been taken in a nerve bundle which in the lower vertebrates runs through the centre of the central canal of the cord, and takes its origin in the optic reflex cells in close relation to the posterior commissure of the brain. More posteriorly (caudad) it probably acquires a connexion with the motor cells of the cord and is looked upon as a means by which the muscles can be made to actively respond to the stimulus of light. It is known as *Reissner's fibre*, and its morphology and physiology have been studied most carefully in cyclostomes and fishes. It is said to be present in the mouse, but hitherto no trace of it has been found in man. It was discovered in 1860, but for forty years has been looked upon as an artifact.

See P. E. Sargent, "Optic Reflex Apparatus of Vertebrates," *Bull. Mus. Comp. Zool. Harvard*, vol. xlv. No. 3 (July, 1904); also for general details R. Wiedersheim, *Comparative Anatomy of Vertebrates* (London, 1907); Lenhossek, *Bau des Nervensystems* (1895). (F. G. P.)

SURGERY OF THE SPINE AND SPINAL CORD

Fracture of the spine may occur from indirect violence, as when a man falls from a height upon his head, or in a sitting position; or it may result from direct violence, as when he is hanged, or as when he is run over by a loaded van, or in a fall from a height across a beam. The vertebrae above the fracture being displaced from those below it, the spinal cord is generally torn across, and the parts of the trunk, or the limbs, which are supplied by the spinal nerves passing out from the cord below the seat of injury are of necessity cut off from their connexion with the brain, and at once deprived of sensation and of the power of voluntary movement. In some cases of fracture of the spine there is at the time marvellously little constitutional disturbance. The higher up the column that the fracture occurs the more quickly does death ensue. If the fracture is in the middle of the back the patient may linger for several weeks, but even if he is lying upon a water-bed, and even if every care is taken of him, inflammation of the bladder and intractable bed-sores are apt to make their appearance, and his existence becomes truly miserable. Operative surgery is unable to effect much in these cases on account of the spinal cord being generally torn across or hopelessly crushed.

Curvature of the spine may be due to deformity of the bodies of the vertebrae caused by irregular pressure, or to the disintegration of their anterior parts by tuberculous ulceration, known as Pott's disease or spinal caries. Thus the causes of spinal curvature are very different, and it is necessary that the actual condition be clearly recognized or treatment may prove harmful. Briefly, the curvature which is due to tuberculous disease requires absolute and continuous rest; the other calls for well-regulated exercises.

Lateral or rotatory curvature of the spine is a deformity which comes on during the developing period of life, before the bodies of the vertebrae are solidly formed. In young people who are growing rapidly, and whose muscular system is weak, the bad habit of standing, and throwing the weight of the body constantly on one leg, gives rise to a serious tilting of the trunk; or, if, when writing at a desk, they sit habitually in a twisted position, a lateral curvature of the spine is apt to take place. By constant indulgence in these bad habits the spinal column gets permanently set in a faulty position. Sometimes the tilting of the base of the trunk is due to a congenital or acquired difference in the length of the legs. In the concavity of the curve there is increased pressure, and, necessarily, diminished growth; in the convexity of the curve there is diminished pressure with increased growth. The patient's friends probably notice that one shoulder is higher than the other, or that "the hip is growing out," and unless means are taken to alter the abnormal distribution of pressure, the condition becomes worse, until complete ossification checks the further progress of the deformity. The growth of the subject being completed, the deformity ceases to increase. And when the growth is completed and the bones are solid and misshapen the condition is quite incapable of improvement. The usual curvature is one in which there is a convexity of the spine in the chest-region towards the right, with the right shoulder higher than the left. Compensatory curves in the opposite direction form in the loins and neck. Along with the lateral bending of the spine a rotation of the bodies of the vertebrae towards the convexity of the curve takes place, the spinous processes turning towards the concavity of the curve. Since the line of the spinous processes of the vertebrae can be easily traced through the skin, their deviation may mislead the superficial observer as to the actual amount of the curvature.

To counteract this deformity in the earliest stages (and it is in the early stage that treatment effects most), the patient (generally a girl) should be encouraged to walk perfectly erect. Systematic exercises, to strengthen the muscles of the back, ought to be strictly and persistently carried out under the direction of a surgeon with the assistance of a skilled instructor of gymnastics. During the intervals of rest the child should lie upon her back on a firm board, and should avoid taking exercise which gives rise to weariness of the muscles; for whenever the muscles become wearied she will attempt to take up a position which throws the strain on to her ligamentous and bony structures. One of the best exercises is to lay the patient on her face, fix her feet, and encourage her to raise herself by using the muscles of the back. Whilst she hangs from a trapeze the weight of the lower limbs and pelvis will help to straighten the spine as a whole, necessarily diminishing the increased pressure upon the cartilaginous bodies of the vertebrae towards the concavity, and increasing the pressure between the sides of the bodies towards the convexity. It is often a good thing to remove a girl with commencing lateral curvature from the sedentary life of school or town and to let her run wild in the country, exercising her muscles to the full.

If the deformity is due to inequality in the length of the legs, a high boot on the short leg may correct it. In some cases of lateral curvature a tilted seat is useful. Mechanical "spinal supports" are as expensive as they are inefficient. As a rule, indeed, they are positively harmful, in that they add to the weight of the trunk and hinder needful muscular development.

By *kyphosis* is meant an exaggerated degree of roundness of the shoulders. It can be effaced only by constant drillings and exercises whilst the spinal column is still plastic. When once the bones are solid no great improvement is possible. The deformity is sometimes due to short sight. It is well, therefore, to have the child's vision duly tested.

Lordosis is an exaggeration of the normal concavity of the loin-region of the spine. It is most often met with in those cases in which from congenital displacement of the head of the thigh bone, or from old disease of the hip-joint, the subject has acquired the habit of throwing the shoulders back in order to preserve the balance.

Tuberculous disease of the spine (*Pott's disease*), is the result of a deposit of tubercle-germs in the body of the vertebra. Inflammation having thus been set up, ulceration (caries) of the vertebra, or of several vertebrae, occurs, and if the case runs on unchecked extensive abscesses may form in the thigh, loin or groin. The trouble is often begun by a blow or by a sprain of the spine, which, by lowering the power of resistance of the delicate bone, prepares it for the bacillary invasion. The earliest symptoms are likely to be a dull aching in the back with stiffness of the spine. The child complains of being tired, and is anxious to lie down and be left quiet whilst his little companions are running about. If the disease is in the middle part of the spine, pains are complained of in the front of the chest or at the pit of the stomach. Unfortunately such pains are often ascribed to indigestion. If the disease is in the upper part of the spine the pains may be in the head, the shoulders or the arms. If in the loin-region of the spine they are in the lower part of the trunk, the thighs or the legs. (These obscure peripheral pains are often misunderstood and are apt to be attributed to rheumatism). The back is stiff so that the child cannot stoop. In trying to pick up anything from the floor he keeps his back straight and bends his knees. If the disease is in the neck-region he cannot easily look upwards, and, instead of turning his head to look sideways, he wheels round his whole body. In some cases, though the disease is far advanced, there have been no complaints of pain in the back. As the bodies of the vertebrae crumble away, the spine bends forwards under the influence of the weight of the head and of the upper part of the trunk, and a projection may appear in the middle line of the back. In the neck, and in the loin-region, the projection is rarely well marked, but in the chest-region a conspicuous boss may make its appearance—the "hump-back." The projection is often spoken of as an *angular curvature*—a contradiction in terms, for a thing which is angular is not curved. When the deformity is great there may be pressure upon the spinal cord with more or less paralysis in the parts below.

The treatment of tuberculous disease of the spine demands absolute and uninterrupted rest. The best thing is to put the patient flat on his back for as many months as may be found necessary, but not in a close bedroom. If he is compelled to lie in a bedroom the windows should be open night and day. If the patient is a child, he should be laid flat in a box-splint, or upon a thin horsehair mattress, and should be carried out of doors every day—but always lying flat. When the pressure-symptoms, such as the pains in the legs, thighs or arms, the "belly-ache," or the pains in the chest or neck have passed away, a firm leather splint may be moulded on to keep the parts quiet until consolidation has taken place, or a cuirass of poroplastic felt or of plaster of Paris may be applied. The danger in these cases is of leaving off treatment too soon: they must not be hurried, or the trouble will be likely to come back again with, perhaps, increased deformity. If the disease is in the upper part of the dorsal spine, or in the neck-region, a cervical collar of leather, or a double Thomas's hip-splint may be found useful.

In cases of advanced tuberculous disease of the spine, in which the spinal cord is compressed within its bony canal either by the posterior parts of the vertebral bodies or by inflammatory products, or in which, after severe injury, the cord is pressed upon by a displaced piece of bone, the surgeon may think it expedient to open the spinal canal from behind, removing in the procedure the posterior arches (laminae) of the vertebrae. The operation is called by the hybrid word *laminectomy*. Sometimes in the case of tuberculous disease, where the propriety of resorting to the operation is being discussed, the symptoms of the compression begin to clear off and the child makes a complete recovery without being operated on; the moral is that we should wait patiently and give Nature a full chance of doing her work in her own way. The operative treatment of these cases is not highly satisfactory. Still, there are a certain small number of cases in which it may be given a trial.

The treatment of spinal abscess has been greatly influenced by the Listerian method. The collection of broken-down tuberculous material or fluid is not an *abscess* in the usual sense, for it does not contain "pus" or "matter," being, as a rule, destitute of septic micro-organisms. A spinal abscess is therefore no longer drained: it is incised, scraped, washed out, and swabbed dry, the opening being carefully and permanently sewn up. In this way septic germs are effectually excluded from the cavity, and the patient is spared the depressing and tedious discharging of the cavity which so often followed the old methods of treatment. It must be clearly understood, however, that every spinal abscess does not undergo cure after being subjected to the evacuation and closure treatment mentioned above, but that the surgeon is sometimes compelled to use irrigation and drainage.

In 1897 Dr Calot of Berk-sur-Mer reintroduced the method of straightening out the hump of the back, so often left after disease of the spine, by stretching the child on a flat table and dealing with the hump, under chloroform, with what is commonly known as "brute force." A considerable number of hump-backed children on the Continent as well as in England and America were thus dealt with, but it is doubtful whether the records of those cases, could they all be collected and published, would be found to justify the enthusiasm and publicity with which the method was inaugurated and its details were spread abroad. It is scarcely necessary to say that the forcible straightening of a spine which has developed a hump because tuberculous disease has wrecked the front of the vertebral segments is in no sense a *curative* operation. Diminishing the size of the projection does not cure the tuberculous ulceration of the bones; indeed, it may increase the ulcerative process or determine a scattering of the germs of tubercle throughout the body. The operation has not been accepted by British and American surgeons. In the practice of the foreign surgeon death ensued in three cases out of thirteen that were operated on, and an English surgeon reported fourteen cases "in all of which the deformity had recurred although the spines had been fixed in plaster of Paris after the straightening."

Being deeply placed in the mass of the muscles of the back, and, moreover, being jealously locked within the bony canal of the vertebral column, the spinal marrow or spinal cord was, until the last few years, generally considered to be beyond the reach even of the most enterprising surgeon. Still, like other tissues, it was liable to diseases and injuries. The exact situation of a tumour pressing upon the spinal cord can now be located with great precision by noting the areas of pain and numbness, and the height in the limbs or trunk to which loss of power of voluntary movement ascends, and by noting also whether these effects are symmetrical upon the two sides or appear more upon one side than on the other. By cutting away the posterior parts of certain segments of the vertebral column, tumours of various sorts have been successfully removed from the interior of the canal. Displaced fragments of bone in tuberculous affection of the spine, abscess-contents and inflammatory tissue have also been similarly dealt with. Sir William Macewen of Glasgow and Sir Victor Horsley of London have been pioneers in this development of surgery. In cases of fracture of the spine, with displacement of the vertebrae and compression of the spinal cord, surgeons have also been trying what relief can be afforded by the adoption of bold operative measures, but as in most of these cases of fracture-dislocation the spinal cord is torn right across or crushed beyond hope of repair, active measures cannot be undertaken with much prospect of success.

"*Concussion of the Spine*."—Occasionally one hears persons, whose professional education should have taught them better, speaking or writing of concussion of the spine as if that were in itself a disease. It is an expression which is not infrequently used in an equally comprehensive and incorrect way when the ill-informed person is speaking of the injuries, real or imaginary, of which an individual makes complaint after having met with a severe shake when travelling on a railway. One might as well speak of concussion of the skull as of concussion of the spine, for the spine is but the bony envelope of the spinal cord, as the skull is of the brain. The violent shaking of the spinal cord and the spinal nerves in a serious accident may, however, be followed by some functional disturbance, which may be associated with pains in the back, by numbness and tingling in the limbs, or with muscular weakness. In some cases the disturbance is due to slight haemorrhages into the nerve sheaths, which may clear up with rest and quiet. But when the presence of these obscure symptoms, after a railway accident for instance, becomes the subject of an action-at-law, there is a great chance that they will not pass off until the case is settled in one way or the other. Not, perhaps, that the individual concerned is dishonest in his estimation of them, but because the anxiety of the overhanging lawsuit has so grievously disturbed his mind and altered his perspective that his sense of proportion is for a time in abeyance. After the action-at-law the symptoms may clear up with a rapidity which to some people appears surprising. (E. O.*)

Physiology of the Spinal Cord

The name spinal cord, given by early morphologists to the nervous mass lying in the tubular chamber enclosed by the vertebral column, was doubtless given under the supposition that the organ so named could be treated as an entity. Scientifically, however, it cannot be so treated, either as regards its structure or its function. It is merely a part of that great nervous structure which throughout the length of the body forms the central meeting-place of the nerve-paths arriving from and issuing to all regions with which nerve fibres are in touch. To separate from the rest of this system the part which lies within the spine is an artificial and in many ways misleading provision. This artificial treatment is the outcome of crude ideas drawn from the study of merely the gross form of the bodily parts. But crude as the distinction is, its historic priority has influenced the study of the vertebrate nervous system, not only in regard to morphological description but also in regard to exposition of the functional reactions of the nervous system and even up to the present day. Hence it is still customary arbitrarily to detach certain of the reactions of the nervous system into a separate group and describe that group by itself, simply because they occur in nervous arcs whose central courses in the great central nervous organ lie within that part of it extending along the spine. An additional inconvenience attaching to the mode of description of the nervous system customary in works on human anatomy, is that in such works the parts of the nervous arcs outside the central organ are described apart from it under the term peripheral nerves. This severs artificially structures which are functionally indissolubly united. The study and description of the working of the nervous system is hampered by this unphilosophic subdivision of its structural parts.

To gain a broader and truer point of view as starting-point for understanding the working of the spinal cord one must prepare the exposition by a short reference to the general function of the nervous system in the bodily economy.

Relation to General Nervous System.—An animal of microscopic size may continue throughout its life to be constituted entirely by one single cell. Animals of larger bulk, although each begins its existence as a single cell, attain their development by the multiplication of the original single cell, so that, from it there comes to be formed a coherent mass of cells very many millions in number. In these multicellular animals each of the constituent cells is a minute self-centred organism, individually born, leading its own life and destined for individual death. The corporate power of the complex animal is the sum of the powers of those manifold individual existences, its cells. In the complex animal the several organs, even the most homogeneous, such as muscles or glands, are each composed of many thousands of cells similarly specialized but living each *per se*. The solidarity of action which a complex animal thus built up exhibits is the result of the binding together of the units which compose the complex organism. Of the agencies which integrate the complex animal, one of the most potent is nervous action. A certain number of the unit cells composing the animal are specially differentiated from the rest to bind the whole together by nervous action. These specially differentiated cells are called "neurones." They constitute living threads along which waves of physico-chemical disturbance are transmitted to act as releasing forces for the energy in distant cells, where they finally impinge.

It is characteristic of this nervous system, the system of neurones, that, although ramifying far and wide through the body, it is a continuum from end to end. The peripheral nerves are formed of bundles of neurones lying side by side, but these, although packed close together, are strictly isolated one from another as conductors and remain isolated throughout the whole length of the nerve. The points of functional nexus of the neurones one with another are confined to one region only of the whole system. All their conductive connexions one with another take place solely in the central nervous mass which constitutes the so-called central nervous system, a nervous organ extending axially along the length of the body midway between the body's lateral halves. Thither the neurones converge in vast numbers, those of each body segment converging to that fraction of the central organ which belongs to their body segment. The central nervous organ thus receiving these neurones is, where it lies in the head, called the brain, the rest of it is called in vertebrates the "spinal cord," in vermes and arthropods the "nerve-cord." The central organ not only receives neurones which converge to it from outside, but many of its own neurones thrust out their conductive arms from it as nerve fibres carrying nervous influence outwards to regulate the activity of glands and muscles. In the vertebrata the ingoing neurones for each segment and similarly the out-going neurone fibres are collected into a segmental nerve. To the spinal cord these are each attached by two roots, one dorsal, consisting of the afferent fibres, the other ventral, consisting of the efferent fibres.

The Reflex.—Analysis of function of this nervous system leads to what is termed "the reflex" as the unit of its action. The simplest complete reaction of the system is a reflex. There are many reflexes which are extremely complex, being built up of a number of simpler reflexes combined together. A reflex is a reaction started by the environment acting as a stimulus upon some nerve which communicates the excitement thus started in itself to other nerves by means of its connexions with these in the central nervous organ. The excitement so generated and transmitted finally travels outward from the central organ by one or more of the efferent nerves and through these reaches muscles or glands producing in them its final effect. The muscles and glands are from this point of view termed effector organs. The reaction is therefore "reflected" from the central organ. The nerve structures along which it runs in its trajectory are spoken of as a nervous arc. The whole purpose of the central nervous organ is therefore to bring afferent neurones into touch with efferent neurones. The whole purpose of reflex arcs is to bind one part of the organism to another part in such a way that what the environment is doing to the organism at one place may appropriately call forth or restrain movement or secretion in the muscles or glands possessed by the organism.

Receptor Cells.—There is one condition for the due performance of these reactions which is not provided by the nervous system itself. The afferent neurones are not in most cases so constituted as to be excitable themselves directly by the environment—for instance, they cannot be stimulated by light. Their amenability to the environment, their sensitization to environmental agencies, is effected by special cells adjunct to their peripheral ends. These cells from organs are called *receptors.* They are delicately adapted to be stimulated by this or that particular agent and are classifiable into various species, so that each species is easily excited by a particular agent which is "adequate" for it, and is quite inexcitable or only excitable with difficulty by agencies of other kinds. Thus in the skin some receptors are adapted for mechanical stimuli (touch) and not for thermal stimuli, while others (cold spots, warm spots) are adapted for thermal stimuli and not for mechanical. As far as it is known each afferent neurone is connected with receptors of one species only. The receptors thus confer upon the reflex arcs selective excitability. Each arc is thus tuned to respond to certain stimuli, while other arcs not having that kind of receptor do not respond. The receptors, therefore, while increasing the responsiveness of the organism to the environment, prevent confusion of reactions (inco-ordination) by limiting to particular stimuli a particular reaction.

Proprioceptors.—The system of neurones is thus made accessible to the play of the external world acting on the body. And in addition to those receptors which are stimulated directly by the external world, are others lying within the mass of the organism itself, which are excitable by actions occurring in the organism itself. These are called *proprioceptors.* They are distributed preponderantly in the muscles and structures functionally adjunct to muscle, such as joints, ligaments, fasciae, &c. The reactions induced in such motor structures reflexly in response to environmental stimuli tend therefore secondarily to be followed and accompanied by reflex reactions initiated from proprioceptors.

Conduction.—The process by which the excitement generated in the afferent neurone travels along the reflex arc is known as *conduction.* Conduction along afferent and efferent nerves differs in some important respects from that obtaining in the nerve centre, *i.e.* in the piece of the central nervous system connecting the afferent nerve with the efferent nerve. In a nerve-trunk the excited state set up in it by a stimulus travels along its fibres as wave-like disturbance at a speed of about thirty-three metres per second, and does not alter in intensity or speed in its travel. A nerve-trunk when excited (artificially) at some point along its length transmits the "impulse," *i.e.* the wave-like excited state in both directions, *i.e.* both up and down each fibre, from the point stimulated. This is true whether the fibre is afferent or efferent. The speed of travel of the nervous impulse along the nerve-trunk is practically the same whether the state of excitement, *i.e.* nervous impulse, is weak or intense. The nerve-trunk shows practically no delay in its response to an effective even though weak stimulus and its response ceases practically at once on cessation of the exciting stimulus. When excited by repeated brief stimuli the rhythm of the response corresponds closely with that of the stimuli, even when the frequency of the latter is as high as 100 per second. With momentary stimuli a response even so brief as 2σ can be given by the nerve-trunk. Finally, nerve-trunk conduction is singularly resistant to fatigue, to impoverished blood supply, and to many drugs which powerfully affect reflex actions.

In conduction through the central nervous organ the travel of the nervous impulse exhibits departure from these features. Its intensity is liable to be altered in transit. Its time of transit, especially if it be weak, is much longer than for a similar length of nerve-trunk. Its direction of transmission becomes polarized, that is, confined to one direction along the nervous path. The state of excitement engendered does not subside immediately on cessation of the stimulus, and may outlast the stimulus by many seconds. The rhythm of response to a rhythmic stimulus does not change in correspondence with change in the stimulus-rhythm. A response, however brief the stimulus, is probably never shorter than 50 in duration.

These are striking differences, and morphological study of the structural features of the central organ does not at present suggest how they for the most part arise. It seems certain, however, that in the central organ it is that part which consists of so-called grey matter which forms the place of their occurrence. There the spread of the impulse from one nerve-fibre to others seems clearly due to the fact that each afferent fibre breaks up into branching threadlets which ramify in various directions and terminate in close apposition with other neurones. There has been much dispute as to whether the termination is one of contiguity with the next neurone or of actual continuity with it. The result of recent investigation seems to show that in the vast majority of cases contiguity and not actual homogeneous continuity is the rule in the spinal cord. The point of nexus of one neurone with another is termed the synapse. If synapsis occurs by contiguity and not homogeneous continuity, it is fair to suppose that at it the transmission of nervous impulses must be different from that observable in the homogeneous conducting threads of nerve fibres. The conduction must traverse something of the nature of a membrane. To the properties of synaptic membranes many of the features peculiar to conduction in the grey matter may be due, for instance, the feature of irreversible direction of conduction.

Reflex Reactions.—When the spinal cord is severed at any point the reflex arcs of the portion of the body behind the transection are quite cut off from the rest of the nervous system in front, including the brain. The reflex reactions elicited from the thus isolated region cannot therefore be modified by the action of the higher nervous centres. It is important to see what character these reflexes possess. The higher centres in the brain exercise powers over the motor machinery of the body and in doing so make use of the simpler nervous centres that belong to the segments severally, that is the local nervous centres existing for and in each body segment itself. In the head the local centres are overlaid by higher centres which cannot by any simple severance be separated from them By studying, therefore, the powers of the cord behind a complete spinal transection we can obtain in a comparatively simple way information as to the powers of the purely local or segmental reflex mechanisms.

The so-called "flexion-reflex" of the limb is one of the most accessible of the local reflex reactions which can thus be studied with an isolated portion of the spinal cord as its centre.

Let it be supposed that the limb observed is the hind limb. The three main joints of the limb are the hip, the knee and the ankle. Each of these joints is provided with muscles which flex or bend it, and others which extend or straighten it. It is found that the reflex throws into contraction the flexor muscles of each of these joints. It matters little which of all the various afferent nerves of the limb is stimulated, whichever of these the afferent nerve may be, the centrifuged discharge from the cord goes to practically the same muscles, namely, always to the flexors of the joints.

The centrifuged discharge does not go to the extensor muscles of the limb. However strong the stimulus and however powerful the afferent nerve chosen the spinal centre does not discharge impulses into the extensor muscles, though these muscles receive motor nerves issuing from the very same region of the cord as that supplying motor nerves to the flexor muscles. Not only does the reflex action not discharge motor impulses into the nerves of the extensor muscles, but if the spinal cord happens to be discharging impulses into these nerves when the reflex is evoked this discharge is suppressed or diminished (*inhibited*). The result is that when the reflex occurs not only are the flexor muscles made to contract, but their antagonists, the extensors, are, if in contraction at the same time, thrown out of contraction, that is, relaxed. In this way the latter muscles are prevented from impeding the action of the contracting flexors. This inhibition occurs at the beginning of the reflex action which excites the muscles and continues so long as the flexion-reflex itself continues. It thus prevents other reflexes from upsetting for the time being the due action of the flexion-reflex, for it renders the muscles opposing that reflex less accessible to motor discharge through the spinal cord whatever the quarter whence incitation to that discharge may come.

A feature of this reflex is its graded intensity. A weak stimulus evokes in the flexor muscles a contraction which is weak and in the extensor muscles a relaxation which is slight. Not only is the contraction weak in the individual flexor muscles, but it is limited to fewer of them, and in large muscles seems to involve only limited portions of them.

The duration of the reflex similarly varies directly with the duration of the exciting stimulus applied to the afferent nerve. The time relations of electrical stimuli can be controlled by the experimenter with much precision. In the single induction shock he has at command a stimulus of extreme brevity, lasting only a few millionths of a second. With such stimulus a lower limit is soon found to the brevity of the reflex effect as expressed by muscles. It is found difficult to evoke with brief stimuli reflex contractions so brief as those evoked from the muscle by similar stimuli applied direct to the motor nerve of the muscle. There is reason to think that such stimuli applied to a nerve may evoke one single nerve-impulse. A single nerve impulse generated in a motor nerve causes in the muscle a brief contraction which is called a twitch, and lasts a tenth of a second. A single nerve impulse generated in an afferent nerve sometimes fails on arriving at the spinal centre to evoke any observable reflex effect at all, but if it is effective the muscle contraction tends to be longer than a "twitch," often much longer. It is therefore questioned whether the spinal centre when excited even most briefly ever discharges one single centrifugal impulse only; it seems usually to discharge a short series of such impulses.

Allied to this character is the tendency which even simple spinal reflexes exhibit to continue discharging for a certain time after their exciting stimulus has ceased to be applied. This after-discharge succeeding a strong stimulus may persist even for several seconds.

Refractory Phase.—Besides characters common to all or many spinal reflexes certain spinal reflexes have features peculiar to themselves or exhibited by them in degrees not obvious in other reflexes. One of these features is refractory phase. The scratch-reflex exemplifies this. In the dog, cat, and many other animals the hind limb often performs a rapid scratching movement, the foot being applied to the skin of the shoulder or neck as if to groom the hairy coat in that region. This movement is in the intact animal under control of the brain, and can be executed or desisted from at will. When certain of the higher centres in the brain have been destroyed, this scratching action occurs very readily and in, as it were, an uncontrolled way. When the spinal cord has been severed in the neck this scratching movement of the hind limb can be elicited with regularity as a spinal reflex by merely rubbing the skin of the side of the neck or shoulder, applying there a weak electric current to the skin. In this reflex the stimulus excites afferent nerves connected with the hairs in the skin and these convey impulses to the spinal centres in the neck or shoulder segments, and these in turn discharge impulses into nerve fibres entirely intraspinal passing backward along the cord to reach motor centres in the hind limb region. These motor centres in turn discharge centrifugal impulses into the muscles of the hind limb of the same side of the body as the shoulder which is the seat of irritation. The motor discharge is peculiar in that it causes the muscles of the hind limb to contract rhythmically at a rate of about four contractions per second, and the discharge is peculiar further in that it excites the flexor and extensor muscles of the joints alternately so that at the hip for instance the limb is alternately flexed and extended, each single phase of the movement lasting about an eighth of a second. Now this rhythmic discharge remains the same in rate whether the exciting stimulus applied to the skin be continuous or one of many various rates of repetition. Evidently at some point in the reflex arc there is a mechanism which after reacting to the impulses reaching it remains for a certain brief part of a second unresponsive, and then becomes once more for a brief period responsive, and so on. And this phasic alternation of excitability and inexcitability repeats itself through the continuance of the reflex even when that endures for minutes. The phase of inexcitability is termed the refractory phase. It is important as an essential element in the co-ordination; without it the scratching movement would obviously not be obtained for alternation of flexion and extension is essential to the act. A similar element almost certainly forms part of the co-ordinating mechanism for many other cyclic reflexes, including those of the stepping of the limbs, the movement of the jaw in mastication, the action of the eyelids in blinking, and perhaps the respiratory movements of the chest and larynx.

Fatigue.—Nerve trunks do not easily tire out under stimulation even most prolonged. Reflex actions on the other hand relatively soon tire. Some are more resistant, however, than are others. The flexion-reflex may be continued for ten minutes at a time and the scratch-reflex can be maintained so long. As a reflex tires, the muscular contraction which it causes tends to become less intense and less steady. The relatively rapid onset of fatigue in reflexes is counterbalanced by speedy recovery in repose. A long flexion-reflex, when from fatigue it has become weak, tremulous and irregular, will recommence after 30 seconds' repose with almost the same vigour and steadiness as if it had not recently been tired out.

This character of reflexes is in accordance with their executing movements which for the most part are not under natural circumstances required to last long. Such movements are the taking of a step by a limb, the movement of the jaw in mastication, the descent of the diaphragm in breathing, the withdrawal of the foot or the pinion from a noxious stimulus or the movement of the eyelids to wash off a particle touching the cornea, in all these no very prolonged reflex discharge is required. These natural movements to which the artificially provoked reflexes seem to correspond do not demand prolonged motor activity, or when they do, demand it in rhythmic repetition with intervening pauses which allow repose.

Reflex Postures.—But there are certain reflexes which do persist for long periods at a stretch. These are reflex postures. The hind limbs of the " spinal " frog assume an attitude which is reflex, for it ceases on severance of the afferent spinal roots. This attitude is one of flexion at hip, knee and ankle, resembling the well-known natural posture of the frog as it squats when quiet in the tank. Similarly in the " spinal " dog or cat certain muscles exhibit a slight but persistent contraction. This is seen well in the extensor muscles of the knee. These tonic reflexes are related to attitudes. In the dog and cat they are exhibited by those muscles whose action antagonizes gravity in postures which are usual in the animal, thus the extensors of the knee and hip and shoulder and elbow are in tonic contraction during standing. The reflex arcs concerned in reflex maintenance of this tonic contraction of muscles have been shown in several cases to arise within those muscles, and in those very muscles which themselves exhibit the tonic contraction It is not, however, certain that all muscles exhibit a reflex tonus: for instance, it is not certain that in the dog the tail muscles exhibit such a tonus. And in those muscles which do exhibit the spinal reflex tonus attempts to obtain a similar untiring slight steady reflex contraction by artificial stimuli applied to receptive organs or nerves have failed.

The Spinal Reflex Arcs of the Hind Limb.—When the skin of the limb is stimulated the flexion-reflex already described is evoked. The reflex is excited by nocuous stimuli such as a prick or squeeze applied to the skin anywhere in the limb, but most easily when applied to the foot. Electrical stimuli wherever applied evoke the same reflex. Similarly electrical stimuli applied to any afferent nerve of the limb evoke this reflex, whether the afferent nerve be from skin or from the muscles. Since the reflex always provokes excitation of the flexor muscles and inhibition of the extensor muscles, the result is that central stimulation of the afferent nerve of a flexor muscle excites its own muscle and inhibits its antagonist (reciprocal innervation), while similar stimulation of the afferent nerve of an extensor muscle inhibits its own muscle and excites its antagonist (reciprocal innervation). The reflex flexion of the ipselateral hind limb is commonly accompanied by reflex extension of the opposite hind limb. If the reflex spreads to the fore limb, it produces extension of the same side fore limb with flexion of the crossed fore limb sometimes, but sometimes extension of both fore limbs.

In the dog and cat extension of the ipselateral hind limb can, however, be excited by stimulation of the skin in three limited regions. One of these is the sole of the foot; smooth pressure between the pads excites a strong brief extension. This is called the extensor thrust. It is accompanied by a similar sudden brief extension of all three other limbs. This reflex may be related to the action of galloping, and the pressure which excites resembles that which the weight of the body bears on the pads against the ground.

The two other regions are the skin of the front of the groin supplied by the crural branch of the genito-crural nerve, and the skin just below and mesial to the buttock. These always excite the extensor muscles, not the flexors. They may be concerned with sexual acts.

Reflexes of the Fore Limb.—These resemble those obtainable from the hind limb. The ipselateral reflex is flexion at shoulder, elbow and wrist. The contra lateral fore limb at the same time is extended at shoulder, elbow and wrist. When the reflex spreads to the hind limbs the hind limb of the same side is extended at hip, knee and ankle, that of the crossed side is sometimes flexed at hip, knee and ankle, but sometimes is instead extended at hip, knee and ankle. The reflex sometimes spreads to the neck, causing the head to be turned toward the fore limb, which is the seat of the stimulation.

The Scratch Reflex.—This has already been partly described above. The area from which it can be excited by appropriate stimulation is a large one, namely, a field of skin which is somewhat saddle-shaped having its greatest width transversely across the shoulders. It extends from close behind the pinna back to the loin. The stimuli which are effective are rubbing the skin or lightly pricking it, or lightly pulling on the hairs: also faradisation by a needle electrode whose point is only just inserted among the hairs but not deeper than their roots. If the stimulus be applied to the right hand of the mid-line the right hind limb is flexed at hip and performs the rapid scratching movement described above, and the left hind limb is thrown into steady extension. And conversely, when the stimulus is to the left side of the mid-line.

Each of these reflexes is a co-ordinate reaction. It is seen, therefore, that through the medium of the spinal cord the body behind the head has at command a certain number of reflexes and that each of these manages the skeletal musculature in a co-ordinate way. It will also be clear from the facts mentioned above about these separate reflexes that the fields of muscles worked by these several reflexes is to a large extent common to them all. Thus the reflex excited from the skin of the right hind limb acts on the muscles of that limb and also on those of the three other limbs. So similarly the reflex excited from the left hind limb, and from each fore limb. Study of the inter-relationship between these reflexes shows that by means of the spinal cord not only is co-ordinate action of the muscles ensured for each reflex, but that also the separate reflexes are co-ordinated one with another.

When we examine the relationship holding between individual reflexes we find that some resemble one another in regard to their action upon a particular muscle or group of muscles. On the other hand, some act in opposite ways upon a particular muscle or muscle group. In order to follow the co-ordination effected by the spinal cord in corresponding reflexes together we have to turn to a certain feature in the scheme of construction of the nervous system. This feature is embodied in what is termed the principle of the common path.

Interaction between Reflexes.—At the commencement of every reflex-arc is a receptive neurone extending from the receptive surface to the central nervous organ. This neurone forms the sole avenue which impulses generated at its receptive point can use whithersoever be their destination. This neurone is therefore a path exclusive to the impulses generated at its own receptive point, and other receptive points than its own cannot employ it. A single receptive point may play reflexly upon quite a number of different effector organs. It may be connected through its reflex path with many muscles and glands in many different regions. Yet all its reflex arcs spring from the one single shank or stem, *i.e.* from the one afferent neurone which conducts from the receptive point at the periphery into the central nervous organ.

But at the termination of every reflex arc we find a final neurone, the ultimate conductive link to an effector organ, (muscle or gland). This last link in the chain, *e.g.* the motor neurone, differs obviously in one important respect from the first link of the chain. It does not subserve exclusively impulses generated at one single receptive source, but receives impulses from many receptive sources situate in many and various regions of the body. It is the *sole* path which all impulses, no matter whence they come, must travel if they are to act on the muscle fibres to which it leads.

Therefore, while the receptive neurone forms a private path exclusively serving impulses of one source only, the final or efferent neurone is, so to say, a public path, *common* to impulses arising at any of many sources of reception. A receptive field, *e.g.* an area of skin, is analysable into receptive points. One and the same effector organ stands in reflex connexion not only with many individual points, but even with many various receptive *fields.* Reflexes generated in manifold sense-organs can pour their influence into one and the same muscle. Thus a limb muscle is the *terminus ad quem* of many reflex arcs arising in many various parts of the body. Its motor nerve is a path common to all the reflex arcs which reach that muscle.

Reflex arcs show, therefore, the general features that the initial neurone of each is a *private* path exclusively belonging to a single receptive point (or small group of points); and that finally the arcs embouch into a path leading to an effector organ; and that their final path is common to all receptive points wheresoever they may lie in the body, so long as they have connexion with the effector organ in question. Before finally converging upon the motor neurone the arcs converge to some degree. Their private paths embouch upon *internuncial* paths common in various degree to groups of private paths. The terminal path may, to distinguish it from internuncial common paths, be called *the final common path*. The motor nerve to a muscle is a collection of final common paths.

Certain consequences result from this arrangement. One of these is the preclusion of essential qualitative difference between nerve-impulses arising in different afferent nerves. If two conductors have a tract in common there can hardly be essential qualitative difference between their modes of conduction; and the final common paths must be capable of responding with different rhythms which different conductors impress upon it. It must be to a certain degree aperiodic. If its discharge be a rhythmic process, as from many considerations it appears to be, the frequency of its own rhythm must be capable of being at least as high as that of the highest frequency of any of the afferent arcs that play upon it; and it must be able also to reproduce the characters of the slowest.

A second consequence is that each receptor being dependent for final communication with its effector organ upon a path not exclusively its own but common to it with certain other receptors, such nexus necessitates successive and not simultaneous use of the common path by various receptors using it to *different or opposed* effect. When two receptors are stimulated simultaneously, each of the receptors tending to evoke reflex action that for its end-effect employs the same final common path but employs it in a different way from the other, one reflex appears without the other. The result is *this* reflex or *that* reflex, but not the two together.

In the simultaneous correlation of reflexes some reflexes combine harmoniously, being reactions that mutually reinforce. These may be termed *allied reflexes*, and the neural arcs which they employ *allied arcs*. On the other hand, some reflexes, as mentioned above, are antagonistic one to another and incompatible. These do not mutually reinforce, but stand to each other in inhibitory relation. One of them inhibits the other, or a whole group of others. These reflexes may in regard to one another be termed *antagonistic*; and the reflex or group of reflexes which succeeds in inhibiting its opponents may be termed "prepotent" for the time being.

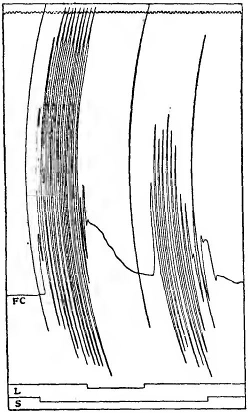
Allied Reflexes.—The action of the principle of the final common path may be instanced in regard to "allied arcs" in the scratch-reflex as follows. If, while the scratch-reflex is being elicited from a skin point at the shoulder, a second point distant 10 mm. from the other point but also in the receptive field of skin, be stimulated, the stimulation at this second point favours the reaction from the first point. This is well seen when the stimulus at each point is of subminimal intensity. The two stimuli, though each unable separately to invoke the reflex, yet do so when applied both at the same time. This is not due to overlapping spread of the feeble currents about the stigmatic poles of the two circuits used. Weak cocainization of either of the two skin poles annuls it. Moreover, it occurs when localized mechanical stimuli are used. It therefore seems that the arcs from the two points, *e.g.* R*a* and R have such mutual relation that reaction of one of them reinforces reaction of the other, as judged by the effect on the final common path.

This reinforcement is really an instance of summation in the final common path. So also is the effect to which Exner has given the name of "bahnung" a phenomenon of frequent occurrence in reflex reactions. Suppose a stimulus (A) be applied which is too weak to elicit the reflex which were it stronger it could evoke. It is found that a second stimulus (B) also of itself too weak to evoke the reflex, will evoke the reflex if applied at a short interval after the application of (A). The two stimuli sum in their effect upon the final common path. The "receptive field" of a reflex is really the common area of commencement of a number of allied arcs. And reflexes whose arcs commence in receptive fields even widely apart may also have "allied" relation. In the bulbo-spinal dog stimulation of the outer digit of the hind foot will evoke reflex flexion of the leg, and stimulation of each of the other digits evokes practically the same reflex; and if stimulation of several of these points be simultaneously combined the same reflex as a result is obtained more readily than if one only of these points is stimulated. And to these stimulations may be added simultaneously stimulation of points in the crossed fore foot; stimulation there yields by itself flexion of the hind leg; and under the simultaneous stimulation of fore and hind foot the flexion of the leg goes on as before, though perhaps more readily; that is, the several individual reflexes harmonize in their effect on the hind limb. Further, to these may be added simultaneous stimulation of the tail and of the crossed pinna; and the reflexes of these stimulations all coalesce in the same way in flexion of the hind limb. Exner has shown that, in exciting different points of the central nervous system itself, points widely apart exert "bahnung" for one another's reactions and for various reflex reactions induced from the skin. Thus reflexes originated at different distant points, and passing through paths widely separate in the brain, converge to the same motor mechanism (final common path) and act harmoniously upon it. Reflex arcs from widely different parts conjoin and pour their influence harmoniously into the same muscle. The motor neurones of a muscle of the knee are the *terminus ad quem* of reflex arcs arising in receptors not only of its own foot, but from the crossed fore foot and pinna and tail, also undoubtedly from the otic labyrinth, olfactory organs and eyes. Thus, if we take as a standpoint any motor nerve to a muscle it consists of a number of motor neurones which are more or less bound into a unit mechanism among the reflex actions of the organism a number can all be brought together as a *group*, because they all in their course converge together upon this motor mechanism, this *final common path*, activate it, and are in harmonious mutual relation with regard to it. They are in regard to it what were termed above "allied" reflexes.

Antagonistic Reflexes.—But not all reflexes connected to one and the same common final path stand to one another in the relation of "allied reflexes." Suppose during the scratch-reflex a stimulus be applied to the foot not of the scratching side, but of the opposite side. The left leg, which is executing the scratch-reflex in response to stimulation of the *left* shoulder skin is cut short in its movement by the stimulation of the *right* foot, although the stimulus at the shoulder to provoke the scratch movement is maintained unaltered all the time. The stimulus to the right foot will temporarily interrupt a scratch-reflex, or will cut it short or will delay its onset; which it does of these depends on the time-relations of the stimuli. The inhibition of the scratch-reflex occurs sometimes when the contraction of the muscles innervated by the reflex conflicting with it is very slight. There is interference between the two reflexes and the one is inhibited by the other. The final common path used by the left scratch-reflex is also common to the reflex elicitable from the right foot. This latter reflex evokes at the opposite (left) knee extension; in doing this it causes steady excitation of extensor neurones of that knee and steadily inhibits the flexor neurones. But the scratch-reflex causes rhythmic excitation of the flexor neurones. Therefore these flexor neurones in this conflict lie as a final common path under the influence of two antagonistic reflexes, one of which would excite them to rhythmical discharge four times a second, while the other would continually repress all discharge in them. There is here an antagonistic relation between reflexes embouching on one and the same final common path.

In all these forms of interference there is a competition, as it were, between the excitatory stimulus used for the one reflex and the excitatory stimulus for the other. Both stimuli are in progress together, and the one in taking effect precludes the other's taking effect as far as the final common path is concerned; and the precise form in which that occurs depends greatly on the time-relations of application of the two stimuli competing against each other.

Again, if, while stimulation of the skin of the shoulder is evoking the scratch-reflex, the skin of the hind foot of the *same* side is stimulated, the scratching may be arrested. Stimulation of the skin of the hind foot by any of various stimuli that have the character of threatening the part with damage causes the leg to be flexed, drawing the foot up by steady maintained contraction of the flexors of the ankle, knee and hip. In this reaction the reflex arc is (under schematic provisions similar to those mentioned in regard to the scratch reflex schema)



Antagonistic Reflexes.

(i.) the receptive neurone, noci-ceptive, from the foot to the spinal segment, (ii.) the motor neurone to the flexor muscle, *e.g.* of hip (a short intra-spinal neurone); a Schalt-zelle (v. Monakow) is probably existent between (i.) and (ii.) but omitted for simplicity. Here, therefore, there is an arc which embouches into the same final common path, FC. The motor neurone FC is a path common to it and to the scratch-reflex arc; both these arcs employ the same effector organ, namely, the knee-flexor, and employ it by the common medium of the final path FC. But though the channels for both reflexes embouch upon the same final common path, the excitatory flexor effect specific to each differs strikingly in the two cases. In the scratch-reflex the flexor effect is an intermittent effect; in the noci-ceptive flexion-reflex the flexor effect is steady and maintained. The accompanying tracing shows the result of conflict between the two reflexes. The one reflex displaces the other at the common path. Compromise is not evident. The scratch-reflex is set aside by that of the noci-ceptive arc from the homonymous foot. The stimulation which previously sufficed to provoke the scratch-reflex is no longer effective, though it is continued all the time. But when the stimulation of the foot is discontinued the scratch-reflex returns. In that respect, although there is no enforced inactivity, there is an *interference* which is tantamount to, if not the same thing as, inhibition. Though there is no cessation of activity in the motor neurone, one form of activity that was being impressed upon it is cut short and another takes its place. A stimulation of the foot too weak to cause more than a minimal reflex will often suffice to completely interrupt, or cut short, or prevent onset of, the scratch-reflex.

The kernel of the interference between the homonymous flexion-reflex and the scratch-reflex is that both employ the same final common path FC to different effect—just as in the interference between the crossed extension-reflex and the scratch-reflex. Evidently, the homonymous flexion-reflex and the crossed extension-reflex both use the same final common path FC. And they *use it to different effect.* The motor neurone to the flexor of the knee being taken as a representative of the final common path, the homonymous flexion-reflex inhibits it from discharging. Hence if, while the direct flexion-reflex is in progress, the crossed foot is stimulated, the reflex of the knee-flexor is inhibited. The crossed extension-reflex therefore inhibits not only the scratch-reflex, but also the homonymous flexion-reflex.

Further, in all these interferences between reflexes the direction taken by the inhibition is *reversible.* Thus, the scratch-reflex is not only liable to be inhibited by, but is itself able to inhibit either the homonymous flexion-reflex or the crossed extension-reflex; the homonymous flexion-reflex is not only capable of being inhibited by the crossed extension-reflex, but conversely in its turn can inhibit the crossed extension-reflex. These interferences are therefore reversible in direction. Certain conditions determine which reflex among two or more competing ones shall obtain mastery over the final common path and thus obtain expression.

Therefore, in regard to the final common path FC, the reflexes that express themselves in it can be grouped into sets, namely, those which excite it in one way, those which excite it in another way, and those which inhibit it. The reflexes composing each of these sets stand in such relation to reflexes of the same set that they are with them "allied reflexes." But a reflex belonging to any one of these sets stands in such relation to a reflex belonging to one of the other sets that it is in regard to the latter an "antagonistic" reflex. This correlation of reflexes about the flexor neurone in the leg, so that some reflexes are mutually allied and some are mutually antagonistic in regard to that neurone, may serve as a paradigm of the correlation of reflexes about every final common path, *e.g.* about every motor nerve to skeletal muscle.

As to the intimate nature of the mechanism which thus, by summation or by interference, gives co-ordination where neurones converge upon a common path, it is difficult to surmise. In the central nervous system of vertebrates, afferent neurones A and B in their convergence toward and impingement upon another neurone Z, towards which they conduct, do not make any lateral connexion directly one with the other—at least, there seems no clear evidence that they do. It seems, then, that the only structural link between A and B is neurone Z itself. Z itself should therefore be the field of coalition of A and B if they transmit "allied" reflexes.

It was argued, from the morphology of the perikaryon, that it must form, in numerous cases, a nodal point in the conductive lines provided by the neurone. The work of Ramón-y-Cajal, van Gehuchten, v. Lenhossek and others, with the methods of Golgi and Ehrlich, establishes as a concept of the neurone in general that it is a conductive unit wherein a number of branches (dendrites) converge towards, meet and coalesce in a single out-going stem (axone). Through this tree-shaped structure the nervous impulses flow, like the water in a tree, from roots to stem. The conduction does not normally run in the reverse direction. The place of junction of the dendrites with one another and with the axone is commonly the perikaryon. This last is therefore a nodal point in the conductive system. But it is a nodal point of particular quality. It is not a nodal point where lines meet to cross one another, nor one where one line splits into many. It is a nodal point where conductive lines run together into one which is the continuation of them all. It is a reduction point in the system of lines. The perikaryon with its convergent dendrites is therefore just such a structure as spatial summation and immediate induction would demand.

The neurone Z may well, therefore, be the field of coalition, and the organ where the summational and inductive processes occur. And the morphology of the neurone as a whole is seen to be just such as we should expect, arguing from the principle of the common path.

With the phenomenon of "interference" the question is more difficult. There it is not clear that the field of antagonism is within the neurone Z itself. The field may be synaptic. We have the demonstration by Verworn that the interference produced by A at Z for impulses from B is not accompanied by any obvious change in excitability of the axone of Z. Z, if itself the seat of inhibition, might have been expected to exhibit that inhibition throughout its extent. This, as tested by its axone, it does not. There exist, it is true, older experiments by Uspensky, Belmondo and Oddi, &c., according to which the threshold of direct excitability of the motor root is lowered by stimulation of the afferent root. This points to an extension of the facilitation effect through the whole motor neurone, conversely to Verworn's demonstration for central inhibition. Verworn's experiment and its result is very clear. It leads us to search for some other mechanism common to A and B to which might be attributable their mutual influence on each other's reactions. But if we admit the conception, argued above, that at the nexus between A and Z, *i.e.* at synapse A Z, and similarly between B and Z, *i.e.* at synapse B Z, there exists a surface of separation, a membrane in the physical sense, a further consequence seems inferable. Suppose a number of different neurones A, B, C, &c., each conducting through its own synapse upon a neurone Z. The synapses A Z, B Z, C Z, &c. are all surfaces or membranes into which Z enters as a factor common to them all. A change of state induced in neurone Z might be expected to affect the surface condition or membrane at all of the synapses, since the condition of Z is a factor common to all those membranes. Therefore a change of state (excitatory or inhibitory) induced in Z by any of the neurones A, B, C, &c., playing upon it would enter as a condition into the nervous transmission at the other synapses from the other collateral neurones. In harmony with this is the spread of refractory state in the neurones as mentioned above. A change in neurone Z induced by neurone A playing upon it, in that case seems to effect its point of nexus with the other neurones B, C, &c., also. It is conceivable that the phenomena of interference may be based in part at least on such a condition. The neurone threshold of Z for stimulation through B will be to some extent a function of events at synapses A Z.

Factors Determining the Sequence.—The formation of a common path from tributary converging afferent arcs is important because it gives a co-ordinating mechanism. There the dominant action of one afferent arc, or set of allied arcs in condominium, is subject to supercession by another afferent arc, or set of allied arcs, and the supercession normally occurs without intercurrent confusion. Whatever be the nature of the physiological process occurring between the competing reflexes for dominance over the common path, the issue of their competition namely, the determination of which one of the competing arcs shall for the time being reign over the common path, is largely conditioned by four factors. These are spinal induction, relative fatigue, relative intensity of stimulus, and the functional species of the reflex.

Spinal Induction.

1. The first of these occurs in two forms, one of which has already been considered, namely, *immediate induction.* It is a form of "bahnung." The stimulus which excites a reflex tends by central spread to facilitate and lower the threshold for reflexes allied to that which it particularly excites. A constellation of reflexes thus tends to be formed which reinforce each other, so that the reflex is supported by allied accessory reflexes, or if the prepotent stimulus shifts, allied arcs are by the induction particularly prepared to be responsive to it or to a similar stimulus.

Immediate induction only occurs between allied reflexes. Its tendency in the competition between afferent arcs is to fortify the reflex just established, or, if transition occur, to favour transition to an allied reflex. Immediate induction seems to obtain with highest intensity at the outset of a reflex, or at least near its commencement. It does not appear to persist long.

The other form of spinal induction is what may be termed *successive induction.* It is in several ways the reverse of the preceding.

In peripheral inhibition, exemplified by the vagus action on the heart, the inhibitory effect is followed by a rebound after-effect opposite to the inhibitory (Gaskell). The same thing is obvious in various instances of the reciprocal inhibition of the spinal centres. Thus, if the crossed-extension reflex of the limb of the "spinal" dog be elicited at regular intervals, say once a minute, by a carefully adjusted electrical stimulus of defined duration and intensity, the resulting reflex movements are repeated each time with much constancy of character, amplitude and duration. If in one of the intervals a strong prolonged (*e.g.* 30″) flexion-reflex is induced from the limb yielding the extensor-reflex movement, the latter reflex is found intensified after the intercurrent flexion-reflex. The intercalated flexion-reflex lowers the threshold for the aftercoming extension-reflexes, and especially increases their after-discharge. This effect may endure, progressively diminishing, through four or five minutes, as tested by the extensor reflexes at successive intervals. Now, as we have seen, *during* the flexion-reflex the extensor arcs were inhibited: *after* the flexion-reflex these arcs are in this case evidently in a phase of exalted excitability. The phenomenon presents obvious analogy to visual contrast. If visual brightness be regarded as analogous to the activity of spinal discharge, and visual darkness analogous to absence of spinal discharge, this reciprocal spinal action in the example mentioned has a close counterpart in the well-known experiment where a white disk used as a prolonged stimulus leaves as visual after-effect a grey image surrounded by a bright ring (Hering's "Lichthof"). This bright ring has for its spinal equivalent the discharge from the adjacent reciprocally correlated spinal centre. The exaltation after-effect may ensue with such intensity that simple discontinuance of the stimulus maintaining one reflex is immediately followed by "spontaneous" appearance of the antagonistic reflex. Thus the flexion-reflex, if intense and prolonged, may, directly its own exciting stimulus is discontinued, be succeeded by a "spontaneous" reflex of extension, and this even when the animal is lying on its side and the limb horizontal—a pose that does not favour the tonus of the extensor muscles. Such a "spontaneous" reflex is the spinal counterpart of the visual "Lichthof." To this spinal induction, as it may be termed, seems attributable a phenomenon commonly met in a flexion-reflex of high intensity when maintained by very prolonged excitation. The reflex flexion is then frequently broken at irregular intervals by sudden extension movements. It would seem, therefore, that some process in the flexion-reflex leads to exaltation of the activity of the arcs of the opposed extension-reflex. An electrical stimulation of the proximal end of the severed nerve of the extensor muscles of the knee (cat), though it does not, in the present writer's experience, directly excite contraction of the extensors of the knee is on cessation often immediately followed by contraction of them.

As examples of the rebound exaltation following on inhibition the following may also serve. The so-called "mark-time" reflex of the "spinal" dog is an alternating stepping movement of the hind limbs which occurs on holding the animal up so that its limbs hang pendent. It can be inhibited by stimulating the skin of the tail. On cessation of that stimulus the stepping movement sets in more vigorously and at quicker rate than before. The increase is chiefly in the amplitude of the movement, but the writer has also seen the rhythm quickened even by 30% of the frequence.

This after-increase might be explicable in either of two ways. It might be due to the mere repose of the reflex centre, the repose so recruiting the centre as to strengthen its subsequent action. But a similar period of repose obtained by simply supporting one limb—which causes cessation of the reflex in both limbs, the stimulus being stretch of the hip-flexors under gravity—is not followed by after-increase of the reflex.

Or the after-increase might result from the inhibition being followed by a rebound to superactivity. This latter seems to be the case. The after-increase occurs even when both hind limbs are passively lifted from below during the whole duration of the inhibitory stimulus applied to the tail. It is the depression of inhibition, and not the mere freedom from an exciting stimulus, that induces a later superactivity. And the reflex inhibition of the knee-extensor by stimulation of the central end of its own nerve is especially followed by marked rebound to superactivity of the extensor itself.

Again, the knee jerk, after being inhibited by stimulation of the hamstring nerve, returns, and is then more brisk than before the inhibition.

By virtue of this spinal contrast, therefore, the extension-reflex predisposes to and may actually induce a flexion-reflex, and conversely the flexion-reflex predisposes to and may actually induce an extension-reflex. This process is qualified to play a part in linking reflexes together in a co-ordinate sequence of successive combination. If a reflex arc A during its own activity temporarily checks that of an opposed reflex arc B, but as a subsequent result induces in arc B a phase of greater excitability and capacity for discharge, it predisposes the spinal organ for a second reflex opposite in character to its own in immediate succession to itself. The writer has elsewhere pointed out the peculiar prominence of "alternating reflexes" in prolonged spinal reactions. It is significant that they are usually cut short with ease by mere passive mechanical interruption of the alternating movement in progress. It seems that each step of the reflex movement tends to excite by spinal induction the step next succeeding itself.

Much of the reflex action of the limb that can be studied in the "spinal" dog bears the character of adaptation to locomotion. This has been shown recently with particular clearness by the observations of Phillipson. In describing the extensor thrust of the limb the writer drew attention at the time to its significance for locomotion. Spinal induction obviously tends to connect to this extensor-thrust flexion of the limb as an after-effect. In the stepping of the limb the flexion that raises the foot and carries it clear of the ground prepares the antagonistic arcs of extension, and, so to say, sensitizes them to respond later in their turn by the supporting and propulsive extension of the limb necessary for progression. In such reflex sequences an antecedent reflex would thus not only be the means of bringing about an ensuing stimulus for the next reflex, but would predispose the arc of the next reflex to react to the stimulus when it arrives, or even induce the reflex without external stimulus. The reflex "stepping" of the "spinal" dog does go on even without an *external skin* stimulus: it will continue when the dog is held in the air. The cat walks well when anaesthetic in the soles of all four feet.

Each reflex movement must of itself generate stimuli to afferent apparatus in many parts and organs—muscles, joints, tendons &c. This probably reinforces the reflex in progress. The reflex obtainable by stimulation of the afferent nerve of the flexor muscles of the knee excites those muscles to contraction and inhibits their antagonistics: the reflex obtainable from the afferent nerve of the extensor muscles of the knee excites the flexors and inhibits their antagonistics.

Where a reflex by spinal induction tends to eventually bring about the opposed reflex, the process of spinal induction is therefore probably reinforced by the operation of any reflex generated in the movement. This would help to explain how it is that a reflex reaction, when once excited in a "spinal" animal, ceases on cessation of the stimulus as quickly as it generally does. Such a reaction must generate in its progress a number of further stimuli and throw up a shower of centripetal impulses from the moving muscles and joints into the spinal cord. Squeezing of muscles and stimulation of their afferent nerves and those of joints, &c., elicit reflexes. The primary reflex movement might be expected, therefore, of itself to initiate further reflex movement, and that secondarily to initiate further still, and so on. Yet on cessation of the external stimulus to the foot in the flexion-reflex the whole reflex comes usually at once to an end. The scratch-reflex, even when violently provoked, ceases usually within two seconds of the discontinuance of the external stimulus that provoked it.

We have as yet no satisfactory explanation of this. But we remember that such reflexes are intercurrent reactions breaking in on a condition of neural equilibrium itself reflex. The successive induction will tend to induce a *compensatory* reflex, which brings the moving parts back again to the original position of equilibrium.

Fatigue.

2. Another condition influencing the issue of competition between reflexes of different source for possession of one and the same final common path is *fatigue*. A spinal reflex under continuous excitation or frequent repetition becomes weaker, and may cease altogether. This decline is progressive, and takes place earlier in some kinds of reflexes than it does in others. In the "spinal" dog the scratch-reflex under ordinary circumstances tires much more rapidly than does the flexion-reflex.

A reflex as it tires shows other changes besides decline in amplitude of contraction. Thus in the flexion-reflex, the original steadiness of the contraction decreases; it becomes tremulous, and the tremor becomes progressively more marked and more irregular. The rhythm of the tremor in the writer's observations has often been about 10 per second. Then phases of greater tremor tend to alternate with phases of improved contraction as indicated by some regain of original extent of flexion of limb and diminished tremor. Apart from these partial evanescent recoveries the decline is progressive. Later, the stimulation being maintained all the time, brief periods of something like complete intermission of the reflex appear, and even of a replacement of flexion by extension. These lapses are recovered from, but tend to recur more and more. Finally, an irregular phasic tremor of the muscles is all that remains. It is not the flexor muscles themselves which tire out, for these, when under fatigue of the flexion-reflex they contract no longer for that reflex, contract in response to the scratch-reflex which also employs them.

Similar results are furnished by the scratch-reflex, with certain differences in accord with the peculiar character of its individual charge. One of these latter is the feature that the individual beats of the scratch-reflex usually become slower and follow each other at slower frequency. Also the beats, instead of remaining fairly regular in amplitude and frequency, tend to succeed in somewhat regular groups. The beats may disappear altogether for a short time, and then for a short time reappear, the stimulus continuing all the while. Here, again, the phenomena are not referable to the muscle, for when excited through other reflex channels, or through its motor nerve directly, the muscle shows its contraction well. Part of the decline of these reflexes under electrical stimulation in the "spinal" dog may be due to reduction of the intensity of the stimulus itself by physical polarization. That does not account in the main for the above described effects. The graphic record of fatigue of the flexion of the scratch-reflex obtained by continued *mechanical* stimulation does not appreciably differ from that yielded under electrical stimulation. The different speed of the decline due to fatigue proceeds characteristically in different kinds of reflex, and in the same kind of reflex under different physiological conditions, *e.g.* "spinal shock": this indicates its determination by other factors than electrical polarization. Polarization has in a number of cases been deferred as far as possible by using equalized alternate shocks applied in opposite directions through the same gilt needle; this precaution has not yielded results differing appreciably from those given by ordinary double shocks or by series of make or break shocks of the same direction. The slowing of the beat in fatigue is also against the explanation by polarization, since merely weakening the stimulus does not lead to a slower beat.

When the scratch-reflex elicited from a spot of skin is fatigued, the fatigue holds for that spot, but does not implicate the reflex as obtained from the surrounding skin. The reflex is, when tired out to stimuli at that spot, easily obtainable by stimulation two or more centimetres away. This is seen with either mechanical or electrical stimuli. When the spot stimulated second is close to the one tired out, the reflex shows some degree of fatigue, but not that degree obtaining for the original spot. This fatigue may be a local fatigue of the nerve-endings in the spot of skin stimulated, to which in experiments making use of electric stimuli some polarization may be added. Yet its local character does not at all necessarily imply its reference to the skin. It may be the expression of a spatial arrangement in the central organ by which reflex arcs arising in adjacent receptors are partially confluent in their approach toward the final common path, and are the more confluent the closer together lie their points of origin in the receptive field. The resemblance between the distribution of the incidence of this fatigue and that of the spatial summation previously described argues that the seat of the fatigue is intraspinal and central more than peripheral and cutaneous; and that it affects the afferent part of the arc inside the spinal cord, probably at the first synapse. Thus, its incidence at the synapse R*a*—P*a* and at R—P would explain its restrictions, as far as we know them, in the scratch-reflex.

The local fatigue of a spinal reflex seems to be recovered from with remarkable speed, to judge by observations on the reflexes of the limbs of the "spinal" dog. A few seconds' remission of the stimulus suffices for marked though incomplete restoration of the reaction. In a few instances there may be seen return of a reflex even during the stimulation under which the waning and disappearance of the reflex occurred. The exciting stimulus has usually in such cases been of rather weak intensity. In the writer's experience these spinal reflexes fade out sooner under a weak stimulus than under a strong one. This seeming paradox indicates that under even feeble intensities of stimulation the threshold of the reaction gradually rises, and that it rises above the threshold value of the weaker stimulus before it reaches that of a stronger stimulus. The scratch-reflex which has ceased to be elicited by a weak stimulus is immediately evoked—often without any sign of fatigue in its motor response—by increasing the intensity of the stimulus applied at the same electrode. The occurrence of fatigue earlier under the weaker stimulus than under the stronger also shows that the fatigue consequent under the weaker stimulus may often be, relatively to the *production of the natural discharge*, greater than when a stronger stimulus is employed. This, which has been of frequent occurrence in the writer's observations on the leg of the "spinal" dog, if obtaining widely in reflex actions, has evident practical importance.

It is easy to avoid in some degree the local fatigue associated with excitation of the scratch-reflex from one single spot in the skin by taking advantage of the spatial summation of stimuli applied at different points in the receptive field. When this was done, a curious result met the writer. The provocation of the reflex has been made through ten separate points in the receptive field, the distance between each member of the series of points and the point next to it being about four centimetres. Each point is stimulated by a double-induction shock delivered twice a second. When this is done a series of scratch movements is elicited, and continues longer than when the stimuli are applied at the same interval, not to succeeding series of skin points but to one point. Thus three or four hundred beats can be elicited in unbroken series. But the series tends somewhat abruptly to cease. If, then, in spite of the cessation of the response, the stimulation be *continued* without alteration during three or four minutes or more, the scratching movement breaks out again from time to time and gives another series of beats, perhaps longer than the first. These experiments indicate that physical polarization at the stigmatic electrode is not answerable for the fading out of the scratch-reflex. It shows also the complexity of the central mechanisms involved in the reflex. The phenomenon recalls Lombard's phases of briskness and fatigue in series of records obtained with the ergograph.

It is interesting to note certain differences between the cessation of a reflex under fatigue and under inhibition. The reflex ceasing under inhibition is seen to fade off without obvious change in the frequency of repetition of the beats, or in the duration of the individual beats. The reflex ceasing under fatigue is seen to show a slower rhythm and a sluggish course for the latter beats, especially for the terminal ones.

Among the signs of fatigue of a reflex action are several suggesting that in it the command over the final common path exercised for the time being by the receptors and afferent path in action becomes less strong, less steady and less accurately adjusted. Under prolonged excitation their hold upon the final common path becomes loosened. This view is supported by the fact that its connexion with the final common path is then more easily cut short and ruptured by other rival arcs competing with it for the final common path in question. The scratch-reflex interrupts the flexion-reflex more readily when the latter is tired out than when it is fresh.

In the hind limb of the "spinal" dog the extensor-thrust is inelicitable during the flexion-reflex. That is to say, when the flexion-reflex is evoked with fair or high intensity the writer has never succeeded in evoking the extensor-thrust, though the flexed posture of the limb is itself a favouring circumstance for the production of the thrust if the flexion be a passive one. But when the flexion-reflex is kept up by appropriate stimulation of a single point over a prolonged time, so that it shows fatigue, the extensor-thrust becomes again elicitable. Its elicitability is, then, not regular nor facile, but it does become obtainable, usually in quite feeble degree at first, later more powerfully. In other words, it can dispossess the rival reflex from a common path when that rival is fatigued, though it cannot do so when the rival action is fresh and powerful.

Again, the crossed extension-reflex cannot inhibit the reflexion of the flexor-reflex under ordinary circumstances if the intensity of the stimulation of the competing arcs be approximately equal; but it can do so when the flexion-reflex is tired.

The waning of a reflex under long-maintained excitation is one of the many phenomena that pass in physiology under the name of fatigue. It may be that in this case the so-called fatigue is really nothing but a negative induction. Its place of incidence may lie at the synapse. It seems a process elaborated and preserved in the selective evolution of the neural machinery. One obvious use attaching to it is the prevention of the too prolonged continuous use of a common path by any one receptor. It precludes one receptor from occupying for long periods an effector organ to the exclusion of all other receptors. It prevents long continuous possession of a common path by any one reflex of considerable intensity. It favours the receptors taking turn about. It helps to ensure serial variety of reaction. The organism, to be successful in a million-sided environment, must in its reaction be many sided. Were it not for such so-called fatigue, an organism might, in regard to its receptivity, develop an eye, or an ear, or a mouth, or a hand or leg, but it would hardly develop the marvellous congeries of all those various sense-organs which it is actually found to possess.

The loosening of the hold upon the common path by so-called fatigue occurs also in paths other than those leading to muscle and effector organs. If instead of motor effects sensual are examined, analogous phenomena are observed. A visual image is more readily inhibited by a competing image in the same visual field when it has acted for some time than when it is first perceived (W. Macdougall).

One point, on a priori grounds, is a natural corollary from the "principle of the common path," as indicated by the experimental findings relative to the incidence of fatigue. The reflex arcs, each a chain of neurones, converge in their course so as to impinge upon and conjoin in links (neurones) common to whole varied groups—in other words, they conjoin to *common paths*. This arrangement culminates in the convergence of many separately arising arcs in the final efferent-root neurone. This neurone thus forms the instrument for many different reflex arcs and acts. It is responsive to them in various rhythm and in various grades of intensity. In accordance with this, it seems from experimental evidence to be *relatively indefatigable.* It thus satisfies a demand that the principle of the common path must make regarding it.

3. In the transition from one reflex to another a final common path changes hands and passes from one master to another. A fresh set of afferent arcs becomes dominant on the supersession of one reflex by the next. Of all the conditions determining which one of competing reflexes shall for the time being reign over a final common path, the *intensity* of reaction of the afferent arc itself relatively to that of its rivals is probably the most powerful. An afferent arc that strongly stimulates is *caeteris paribus* more likely to capture the common path than is one excited feebly. A stimulus can only establish its reflex and inhibit an opposed one if it have intensity. This explains why, in order to produce examples of spinal inhibition, recourse has so frequently been made in past times to *strong* stimuli. A strong stimulus will inhibit a reflex in progress, although a weak one will fail. Thus in Goltz's inhibition of micturition in the "spinal" dog a *forcible* squeeze of the tail will do it, but not, in the present writer's experience, a weak squeeze. So, likewise, any condition which raises the excitability and responsiveness of a nervous arc will give it power to inhibit other reflexes, just as it would if it were excited by a strong stimulus. This is much as in the heart of the Tunicate. There the prepotent spot whence starts the systole lies from time to time at one end and from time to time at the other. The prepotent region at one end which usually dominates the common path is from time to time displaced by local increase of excitability at the other under local distension of the blood-sinuses there.

Intensity.

In judging of intensity of stimulus the situation of the stimulus in the receptive field of the reflex has to be remembered. One and the same physical stimulus will be weak if applied near the edge of the field, though strong if applied to the focus of the field.

Crossed reflexes are usually less easy to provoke, less reliable of obtainment, and less intense than are direct reflexes. Consequently we find crossed reflexes usually more easily inhibited and replaced by direct reflexes than are these latter by those former. Thus the crossed stepping-reflex is easily replaced by the scratch-reflex, though its stimulus be continued all the time, and though the scratch-reflex itself is not a very potent reflex. But the reverse can occur with suitably adjusted intensity of stimuli.

Again, the flexion-reflex of the dog's leg is, when fully developed, accompanied by extension in the opposite leg. This crossed extensor movement, though often very vigorous, may be considered as an accessory and weaker part of the whole reflex, of which the prominent part is flexion of the homonymous limb. When the flexion-reflex is elicitable poorly, as, for instance, in spinal shock or under fatigue or weak excitation, the crossed extension does not accompany the homonymous flexion and does not appear. But, where the flexion-reflex is well developed, if not merely one but *both* feet be stimulated simultaneously with stimuli of fairly equal intensity, steady flexion at knee, hip and ankle results in *both* limbs, and extension occurs in neither limb. The contralateral part of each reflex is inhibited by the homolateral flexion of each reflex. In other words, the more intense part of each reflex obtains possession of the final common paths at the expense of the less intense portion of the reflex. But if the intensity of the stimuli applied to the right and left feet be not closely enough balanced, the crossed extension of the reflex excited by the stronger stimulus is found to exclude even the homonymous flexion that the weaker stimulus should and would otherwise evoke from the leg to which it is applied.

It was pointed out above that in a number of cases the transference of control of the final common path FC from one afferent arc to another is *reversible.* The direction of the transference can *caeteris paribus* be easily governed by making the stimulation of this receptor or that receptor the more intense. A factor largely determining whether a reflex succeed another or not is therefore intensity of stimulus.

4. A fourth main determinant for the issue of the conflict between rival reflexes seems the functional species of the reflexes. Reflexes initiated from a species of receptor apparatus that may be termed *noci-ceptive* appear to particularly dominate the majority of the final common paths issuing from the spinal cord. In the simpler sensations we experience from various kinds of stimuli applied to our skin there can be distinguished those of touch, of cold, of warmth and of pain. The adequate stimuli for the first-mentioned three of these are certainly different; mechanical stimuli, applied above a certain speed, which deform beyond a certain degree the resting contour of the skin surface, seem to constitute *adequate* stimuli for touch. Similarly the cooling or raising of the local temperature, whether by thermal conduction, radiation, &c., are *adequate* for the cold and warmth sensations. The organs for these three sensations have by stigmatic stimuli been traced to separate and discrete tiny spots in the skin. In regard to skin-pain it is held by competent observers, notably by V. Frey and Kiesow, that skin-pain likewise is referable to certain specific nerve-endings. In evidence of this it is urged that mechanical stimuli applied at certain places excite sensations which from their very threshold upward possess unpleasantness, and as the intensity of the stimulus is increased, culminate in "physical pain." The sensation excited by a mechanical stimulus applied to a touch-spot does not evoke pain, however intensely applied, so long as the stimulation is confined to the touch-spot. The threshold value of mechanical stimuli for touch-spots is in general lower than it is for pain-spots; and conversely the threshold value of electrical stimuli for touch-spots is in general higher than it is for the spots yielding pain. Similarly it is said that stimulation of a cold spot or of a warm spot does not, however intense, evoke, so long as confined to them, sensations of painful quality. But pain can be excited not only by strong mechanical stimuli and by electrical stimuli, but by cold and by warmth, though the threshold value of these latter stimuli is higher for pain than for cold and warm spots. If these observations prove correct there exist, therefore, numerous specific cutaneous nerve-fibres evoking pain.

Species of Reflex.

A difficulty here is that sensory nerve-endings are usually provided with sense organs which lower their threshold for stimuli of one particular kind while raising it for stimuli of all other kinds; but these pain-endings in the skin seem almost equally excited by stimuli of such different modes as mechanical, thermal conductive, thermal radiant, chemical and electrical. That is, they appear *anelective* receptors. But it is to be remarked that these agents, regarded as excitants of skin-pain, have all a certain character in common, namely this, that they become *adequate* as excitants of pain when they are of such intensity as *threatens damage to the skin.* And we may note about these excitants that they are *all able to excite nerve* when applied to naked nerve *directly.* Now there are certain skin surfaces from which, according to most observers, pain is the only species of sensation that can be evoked. This is alleged, for instance, of the surface of the cornea—a modified piece of skin. The histology of the cornea reveals in its epithelium nerve-endings of but one morphological kind; that is, the ending by naked nerve-fibrils that pass up among the epithelial cells. Similar nerve-endings exist also in the epidermis generally. It may therefore be that the nerve-endings subserving skin-pain are free naked nerve-endings, and the absence of any highly evolved specialized end-organ in connexion with them may explain their fairly equal amenability to an unusually wide range of different kinds of stimuli. Instead of but one kind of stimulus being their adequate excitant, they may be regarded as adapted to a whole group of excitants, a group of excitants which has in relation to the organism one feature common to all its components, namely, a *nocuous* character.

With its liability to various kinds of mechanical and other damage, in a world beset with dangers amid which the individual and species have to win their way in the struggle for existence, we may regard nocuous stimuli as part of a normal state of affairs. It does not seem improbable, therefore, that there should under selective adaptation attach to the skin a so-to-say *specific sense of its own injuries*. As psychical adjunct to the reactions of that apparatus we find a strong displeasurable effective quality in the sensations they evoke. This may perhaps be a means for branding upon memory, of however rudimentary kind, a feeling from past events that have been perilously critical for the existence of the individuals of the species. In other words, if we admit that damage to such an exposed sentient organ as the skin must in the evolutionary history of animal life have been sufficiently frequent in relation to its importance, then the existence of a specific set of nerves for skin-pain seems to offer no genetic difficulty, any more than does the clotting of blood or innate immunity to certain diseases. That these nerve-endings constitute a distinct species is argued by their all evoking not only the same species of sensation, but the same species of reflex movement as regards "purpose," intensity, resistance to "shock," &c. And their evolution may well have been unaccompanied by evolution of any specialized end-organ, since the naked free nerve-endings would better suit the wide and peculiar range of stimuli, reaction to which is in this case required. A low threshold was *not* required because the stimuli were all intense, intensity constituting their harmfulness; but response to a wide range of stimuli of *different* kinds was required, because harm might come in various forms. That responsive *range* is supplied by naked nerve itself, and would be cramped by the specialization of an end-organ. Hence these nerve-endings remained free.

It is those areas, stimulation of which, as judged by analogy, can excite pain most intensely, and it is those stimuli which, as judged by analogy, are most fitted to excite pain which, as a general rule, excite in the "spinal" animal—where pain is of course non-existent—the *prepotent* reflexes. If these are reactions to specific pain-nerves, this may be expressed by saying that the nervous arcs of pain-nerves, broadly speaking, dominate the spinal centres in peculiar degree. Physical pain is thus the psychical adjunct of an imperative protective reflex. It is preferable, however, since into the merely spinal and reflex aspect of the reaction of these nerves no sensation of any kind can be shown to enter, to avoid the term "pain-nerves." Remembering that the feature common to all this group of stimuli is that they threaten or actually commit damage to the tissue to which they are applied, a convenient term for application to them is *nocuous*. In that case what from the point of view of *sense* are cutaneous pain-nerves are from the point of view of *reflex-action* conveniently termed *noci-ceptive* nerves.

In the competition between reflexes the noci-ceptive as a rule dominate with peculiar certainty and facility. This explains why such stimuli have been so much used to evoke reflexes in the spinal frog, and why, judging from them, such "fatality" belongs to spinal reflexes.

One and the same skin surface will in the hind limb of the spinal dog evoke one or other of two diametrically different reflexes according as the mechanical stimulus applied be of noxious quality or not, a harmful insult or a harmless touch. A needle-prick to the planta causes invariably the drawing up of the limb—the flexion-reflex. A harmless smooth contact, on the other hand, causes extension—the extensor-thrust above described. This flexion is therefore a noci-ceptive reflex. But the scratch-reflex—which is so readily evoked by simple light irritation of the skin of the shoulder—is relatively mildly noci-ceptive. When the scratch-reflex and the flexion-reflex are in competition for the final neurone common to them, the flexion-reflex more easily dispossesses the scratch-reflex from the final neurone than does the scratch-reflex the flexion-reflex. If both reflexes are fresh, and the stimuli used are such as, when employed separately, evoke their reflexes respectively with some intensity, in my experience it is the flexion-reflex that is usually prepotent. Yet if, while the flexion-reflex is being moderately evoked by an appropriate stimulus of weak intensity, a strong stimulus suitable for producing the scratch-reflex is applied, the steady flexion due to the flexion-reflex is replaced by the rhythmic scratching movement of the scratch-reflex, and this occurs though the stimulus for the flexion-reflex is maintained unaltered. When the stimulus producing the scratch is discontinued the flexion-reflex reappears as before. The flexion-reflex seems more easily to dispossess the scratch-reflex from the final common paths than can the scratch-reflex dispossess the flexion-reflex. Yet the relation is reversible—by heightening the intensity of the stimulus for the scratch-reflex or lowering that of the stimulus for the flexion-reflex.

In decerebrate rigidity, where a tonic reflex is maintaining contraction in the extensor muscles of the knee, stimulation of the noci-ceptive arcs of the limb easily breaks down that reflex. The noci-ceptive reflex dominates the motor neurone previously held in activity by the postural reflex. And noci-ceptive reflexes are relatively little depressed by "spinal shock."

Noci-ceptive arcs are, however, not the only spinal arcs which in the intact animal, considered from the point of view of sensation, evoke reactions rich in affective quality. Beside those receptors attuned to react to direct *noxa*, the skin has others, concerned likewise with functions of vital importance to the species and colligate with sensations similarly of intense affective quality; for instance, those concerned with sexual functions. In the male frog the sexual clasp is a spinal reflex. The cord may be divided both in front and behind the brachial region without interrupting the reflex. Experiment shows that from the spinal male at the breeding season, and also at other times, this reflex is elicited by any object that stimulates the skin of the sternal and adjacent region. In the intact animal, on the contrary, other objects than the female are, when applied to that region, at once rejected, even though they be wrapped in the fresh skin of the female frog and in other ways made to resemble the female. The development of the reflex is not prevented by removal of the testes, but removal of the seminal reservoirs is said to depress it, and their distension, even by indifferent fluids, to exalt it. If the skin of the sternal region and arms is removed the reflex does not occur. Severe mutilation of the limbs and internal organs does not inhibit the reflex, neither does stimulation of the sciatic nerve central to its section. The reflex is, however, depressed or extinguished by strong chemical and pathic stimuli to the sternal skin, at least in many cases. The tortoise exhibits a similar sexual reflex of great spinal potency.

It would seem a general rule that *reflexes arising in species of receptors which considered as sense-organs provoke strongly affective sensation* caeteris paribus *prevail over reflexes of other species when in competition with them for the use of the "final common path."* Such reflexes override and set aside with peculiar facility reflexes belonging to touch organs, muscular sense-organs, &c. As the sensations evoked by these arcs, *e.g.* "pains," exclude and dominate concurrent sensations, so do the reflexes of these arcs prevail in the competition for possession of the common paths. They seem capable of *pre-eminent intensity* of action.

Of all reflexes it is the tonic reflexes, *e.g.* of ordinary posture, that are in the writer's experience the most *easily* interrupted by other reflexes. Even a weak stimulation of the noci-ceptive arcs arising in the foot often suffices to lower or abolish the knee-jerk or the reflex extensor tonus of the elbow or knee. If various *species* of reflex are arranged, therefore, in their order of potency in regard to power to interrupt one another, the reflexes initiated in receptors which considered as sense-organs excite sensations of strong affective quality lie at the upper end of the scale, and the reflexes that are answerable for the postural tonus of skeletal muscles lie at the lower end of the scale. One great function of the tonic reflexes is to maintain habitual attitudes and postures. They form, therefore, a nervous background of active equilibrium. It is of obvious advantage that this equilibrium should be easily upset, so that the animal may respond agilely to the passing events that break upon it as intercurrent stimuli.

Results.—Intensity of stimulation, fatigue and freshness, spinal induction, functional species of reflex, are all, therefore, physiological factors influencing the result of the interaction of reflex-arcs at a common path. It is noticeable that they all resolve themselves ultimately into *intensity of reaction*. Thus, intensity of stimulus means as a rule intensity of reaction. Those species of reflex which are habitually prepotent in interaction with others are those which are habitually intense; those specially impotent in competition are those habitually feeble in intensity, *e.g.* skeletal muscular tone. The tonic reflexes of attitude are of habitually low intensity, easily interfered with and temporarily suppressed by intercurrent reflexes, these latter having higher intensity. But these latter suffer fatigue relatively early, whereas the tonic reflexes of posture can persist hour after hour with little or no signs of fatigue. Fatigue, therefore, in the long run advantageously redresses the balance of an otherwise unequal conflict. We can recognize in it another agency working toward that plastic alternation of activities which is characteristic of animal life and increases in it with ascent of the animal scale.

The high variability of reflex reactions from experiment to experiment, and from observation to observation, is admittedly one of the difficulties that has retarded knowledge of them. Their variability, though often attributed to general conditions of nutrition, or to local blood-supply, &c., seems far more often due to changes produced in the central nervous organ by its own functional conductive activity apart from fatigue. This functional activity itself causes from moment to moment the temporary opening of some connexions and the closure of others. The chains of neurones, the conductive lines, have been, especially in recent years, by the methods of Golgi, Ehrlich, Apathy, Cajal and others, richly revealed to the microscope. Anatomical tracing of these may be likened, though more difficult to accomplish, to tracing the distribution of blood vessels after Harvey's discovery had given them meaning, but before the vasomotor mechanism was discovered. The blood vessels of an organ may be turgid at one time, constricted almost to obliteration at another. With the conductive network of the nervous system the temporal variations are even greater, for they extend to absolute withdrawal of nervous influence. Under reflex inhibition a skeletal muscle may relax to its post-mortem length, *i.e.* there may then be no longer evidence of even a tonic influence on it by its motor neurone. The direction of the stream of liberation of energy along the pattern of the nervous web varies from minute to minute. The final common path is handed from some group of a *plus* class of afferent arcs to some group of a *minus* class, or of a rhythmic class, and then back to one of the previous groups again, and so on. The conductive web changes its functional pattern with certain limits to and fro. It changes its pattern at the entrances to common paths. The changes in its pattern occur there in virtue of interaction between rival reflexes, "interference." As a tap to a kaleidoscope, so a new stimulus that strikes the receptive surfaces causes in the central organ a shift of functional pattern at various synapses. The central organ is a vast network whose lines of conduction follow a certain scheme of pattern, but within that pattern the details of connexion are, at the entrance to each common path, mutable. The grey matter may be compared with a telephone exchange, where, from moment to moment, though the end-points of the system are fixed, the connexions between starting-points and terminal points are changed to suit passing requirements, as the functional points are shifted at a great railway junction. In order to realize the exchange at work, one must add to its purely spatial plan the temporal datum that within certain limits the connexions of the lines shift to and fro from minute to minute. An example is the "reciprocal innervation" of antagonistic muscles—when one muscle of the antagonistic couple is thrown into action the other is thrown out of action. This is only a widely spread case of the general rule that antagonistic reflexes interfere where they embouch upon the same final common paths. And that general rule is part of the general principle of the mutual interaction of reflexes that impinge upon the same common path. *Unlike reflexes have successive but not simultaneous use of the common path; like reflexes mutually reinforce each other on their common path.* Expressed teleologically, *the common path, although economically subservient for many and various purposes, is adapted to serve but one purpose at a time. Hence it is a co-ordinating mechanism and prevents confusion by restricting the use of the organ, its minister, to but one action at a time.*

In the case of simple antagonistic muscles, and in the instances of simple spinal reflexes, the shifts of conductive pattern due to interaction at the mouths of common paths are of but small extent. The co-ordination covers, for instance, one limb or a pair of limbs. But the same principle extended to the reaction of the great arcs arising in the projicient receptor organs of the head, *e.g.* the eye, which deal with wide tracts of musculature *as a whole*, operates with more multiplex shift of the conductive pattern. Releasing forces acting on the brain from moment to moment shut out from activity whole regions of the nervous system, as they conversely call vast other regions into play. *The resultant singleness of action from moment to moment is a keystone in the construction of the individual whose unity it is the specific office of the nervous system to perfect.* The interference of unlike reflexes and the alliance of like reflexes in their action upon their common paths seem to lie at the very root of the great psychical process of "attention."

The spinal cord is not only the seat of reflexes whose "centres" lie wholly within the cord itself; it supplies also conducting paths for nervous reactions initiated by impulses derived from afferent spinal nerve, but involving mechanisms situate altogether headward of the cord, that is to say, in the brain. Many of these reactions affect consciousness, occasioning sensations of various kinds. In regard to the part played by spinal conduction in subserving these sensual reactions a question of practical rather than theoretical importance has been as yet the chief aim of inquiry. The inquiry has been in fact whether the impulses concerned in evoking the various species of sensations follow in their headward course along the cord certain discrete paths occupying separable fractions of the cross-area of the cord, and if they are thus confined to discrete paths in what parts of the cross-area of the cord do these parts lie. This "localization" problem has as yet been almost the sole problem attacked, and therefore, despite its limited scope and interest, the results attained in it may be briefly mentioned here.

Localization.—The sensations usually grouped under the name of touch may with advantage, as shown by Head, be distinguished from the point of view of their practical elicitation into superficial and deep. The former of these are referable to stimulation of afferent nerve-fibres distributed actually to the skin, the latter to stimulation of deeper afferents subjacent to the skin. The touch-fibres belonging to the skin proper are further subdivisible, as Head has shown, into two kinds. One kind, the *protopathic*, yield sensations so suffused with disagreeable affective tone (skin-pain) that they may for the present purpose be considered pain-nerves, and the description of their spinal connexions be relegated to the paragraph dealing with the spinal path for pain. The other kind, the *epicritic*, are those which react to tangible stimuli lightly applied, such as stroking the skin with a loose pledget of cotton wool or the light touching of the skin with a pin's head or a blunt pencil point. Deep touch, on the other hand, involves afferent nerve fibres supplied by nerve-trunks not classed as cutaneous, but probably largely muscular in the sense that they run to muscles and contain side by side the afferent fibres in question and the efferent nerve-fibres causing muscular contraction. Head has brought forward clear evidence that though the afferent fibres subserving the epicritic tactual sense of the skin and deep touch of subcutaneous origin run so separate a course in the peripheral nerves, the spinal fibres constituting the intraspinal headward-running paths from these two kinds of peripheral touch-fibres, the epicritic and the deep, to the brain, lie together and are implicated together by injuries of the spinal cord. In this sense there is, therefore, in the cord a tactual path. The question is, therefore, what course does this path follow in the cord? In the first place it must be noted that the path contains a synapse for the peripheral neurone whether belonging to the epicritic tactual group or to the deep tactual group ends in the cord, probably not far, *i.e.* not more than four or five segments, from its place of entrance. The rest of the headward path must therefore run through one secondary neurone at least, it may be through a series of such arranged as a headward running line of relays. It is, however, more probable that one long secondary neurone reaching the bulb covers the whole of the remaining spinal part of the trajectory. The part of the headward-running path formed by the intraspinal part of the peripheral neurone (primary afferent neurone) lies certainly in the dorsal column of the cord of the same lateral half as the side from which the neurone entered, *i.e.* in the right dorsal column if the neurone entered by a spinal root of the right side. The secondary neurone continuing the path lies, however, in the ventral column of the crossed half of the cord. The junction or synapse between the primary and secondary neurone lies, of course, in the grey matter of the spinal cord.

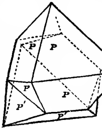
The spinal path of impulses which when they reach the brain occasion pain has been determined chiefly in regard to pain referred to the skin. The primary afferent neurones bringing these impulses to the cord are the protopathic of Head mentioned above. These, there is much evidence to show, terminate in the grey matter of the cord not far from their point of entrance into the cord, that is, they terminate intraspinally nearer their point of entrance than do the corresponding primary afferent neurones for touch. From the local spinal grey matter the pain-path is continued headward in the lateral white columns of the cord by secondary afferent neurones. These secondary afferent neurones run chiefly in the lateral column of the opposite half of the cord from that which the primary afferent neurones entered; but some run up the lateral column of the same side as that by which the primary neurones entered. The synapse between the primary afferent neurone and the secondary afferent neurone of this path lies probably in the grey matter called substantia gelatinosa of the dorsal horn.

The spinal path taken by the impulses concerned with sensations of heat and cold seems to agree closely with that taken by the impulses subserving skin pain. The position of the nerve-fibres belonging to the secondary afferent neurones of the pain and temperature path has been fairly successfully identified with that of the spinal tract called Gowers' tract. The uncrossed portion of the temperature path appears, however, to be relatively smaller as compared with its crossed portion than is that of pain.

There is much evidence that impulses contributory to "muscular sense" pass headward along the spinal cord and in their course remain for the most part uncrossed. This course would in so far agree with the course taken by the intraspinal continuations of the primary afferent neurones which form the long fibres of the dorsal columns. These are known to run to the bulb without transgressing the median plane at all. In addition to this uncrossed tract there is another, namely, that offered by the dorsal cerebellar tract, a tract of secondary neurones connected through the grey matter of the vesicular column of Clarke with primary afferent neurones of the ipselateral side. Either or both of these uncrossed tracts may be the path taken by the impulses subserving muscular sense, and there is experimental evidence in favour of such a possibility, but the question cannot be considered as definitely answered at present.

Besides the paths followed by headward-running impulses the spinal cord contains paths for impulses passing along it backwards from the brain. These paths lie almost entirely in the ventrolateral columns of the cord. The fibres of which they are composed cross but little in the cord. Their sources are various, some come from the hind brain and some from the mid brain, and in the higher mammalia, especially in man and in the anthropoid apes, a large tract of fibres in the lateral column (the crossed pyramidal tract) comes from the cortex of the neopallium of the fore brain. This last tract is the main medium by which impulses initiated by electrical stimulation of the motor cortex reach the moto-neurones of the cord and through them influence the activity of the skeletal muscles. Of the function of the other tracts descending from the brain into the cord little is known except that mediately or immediately they excite or inhibit the spinal moto-neurones by various levels. How they harmonize one with another in their action or what their purpose in normal life may be is at present little more than conjecture. Such terms, therefore, as "paths for volition," &c., are at present too schematic in their basis to warrant their discussion here. (C. S. S.)

SPINEL, a name now given to a group of minerals, of which the typical member is a magnesium aluminate, sometimes used as a gem-stone, to which the term "spinel" was originally restricted. The name comes from the French *spinelle* (diminutive of Lat. *spina*), perhaps suggested by the sharp angles of the crystals. All spinels crystallize in the cubic system, usually in octahedra, and often twinned as in the accompanying figure, which is a form so characteristic as to be called the "spinel twin." The hardness of spinel is about that of topaz (8) and its specific gravity near that of diamond. Professor A. H. Church gives the range in variously coloured spinels as 3·582 to 3·715. Pure spinel is colourless, but most varieties are coloured, no doubt in many cases with iron and probably in some with chromium. The deep red spinel is known as "spinel-ruby," or "ruby-spinel," and has often been taken for true ruby, from which it is distinguished, however, by being singly refracting and therefore not dichroic, as well as by its inferior hardness and density. The "balas ruby" is a rose-red spinel, said to derive its name from Balkh, the capital of Badakshan (Balaxia), where it occurs with rubies, and was formerly worked, chiefly in the Shighnan valley, in the upper Oxus basin. Rubicelle is a spinel in which the red colour tends to orange, whilst in almandine-spinel it passes into violet. Stones of the colour of vinegar are called vinegar-spinel. When the colour is blue the mineral is known as sapphire-spinel, and when green as chloro-spinel.



The spinels used in jewelry are found mostly in gem-gravels, where, however, the octahedral form is often well preserved. The chief localities are Ceylon, Siam and Upper Burma. In all these localities the spinels accompany the coloured corundums, and their close association with true rubies led Tavernier to call spinel "the mother of ruby." Formerly there was much confusion between the two minerals, and probably many stones described as monster rubies have been spinels. The great historic "ruby" set in the Maltese cross in front of the Imperial state crown of England is really a spinel. This fine stone was given to Edward the Black Prince by Pedro the Cruel, king of Castile, on the victory of Najera in 1367, and it was afterwards worn by Henry V. at the battle of Agincourt, when it narrowly escaped destruction. V. Ball described, in 1894, a spinel weighing 133½ carats, engraved with a Persian inscription, then in the possession of Lady Carew.

All the isomorphous minerals known as the group of spinellids, of which spinel is the type, crystallize in regular octahedra and have a composition conforming to the general formula $R''R_2'''O_4$ ($=R''O{\cdot}R_2'''O_3$). Ordinary spinel is $MgAl_2O_4$. A black opaque spinel in which Fe partly replaces Mg is known as pleonaste (πλεονάστος, abundant, from the number of faces on certain crystals) or ceylonite, from the island of Ceylon, but sometimes written ceylanite. It occurs in gneiss, often with cordierite, and is found also in the ejected blocks of Monte Somma, Vesuvius. Large crystals come from Warwick and Amity, Orange county, New York, U.S.A. The black spinels are generally green or brown when viewed in thin sections by transmitted light. In some cases spinel is evidently a result of contact metamorphism, whilst in others it has crystallized out of a molten magma, as illustrated by the experiments of J. Morozewicz. A chrome-spinel with the formula (Mg,Fe) $(Al,Fe,Cr)_2O_4$ is named picotite, after Picot de la Peyrouse, who described it. Picotite occurs in the form of black grains and crystals in certain olivine rocks and in serpentine. A black iron-spinel ($FeAl_2O_4$), found in the granulites of Saxony and Bohemia, is known as hercynite from the Hercynian Forest. A zinc-spinel ($ZnAl_2O_4$), occurring in talcose slate near Falun in Sweden, is named gahnite, after its discoverer J. G. Gahn; whilst it has also been termed automolite from Gr. αὐτόμολος, a deserter, in allusion to the occurrence of zinc in a mineral where it was unexpected. The group of spinellids includes, as its extreme members, magnetite ($Fe''Fe_2'''O_4$) and chromite ($FeCr_2O_4$) (*q.v.*). (F. W. R.*)

SPINELLO ARETINO (*c.* 1330–*c.* 1410), Italian painter, the son of a Florentine named Luca, who had taken refuge in Arezzo in 1310 when exiled with the rest of the Ghibelline party, was born at Arezzo about 1330. Spinello was a pupil of Jacopo di Casentino, a follower of Giotto, and his own style was a sort of link between the school of Giotto and that of Siena. In the early part of his life he worked in Florence as an assistant to his master Jacopo while painting frescoes in the church of the Carmine and in Sta Maria Novella. Between 1360 and 1384 he was occupied in painting many frescoes in and near Arezzo, almost all of which have now perished. After the sack of Arezzo in 1384 Spinello returned to Florence, and in 1387–1388 with some assistants covered the walls and vault of the sacristy of S. Miniato near Florence with a series of frescoes, the chief of which represent scenes from the life of St Benedict. These still exist, though in a sadly restored condition; they are very Giotto-like in composition, but have some of the Siena decorative brilliance of colour. In 1391–1392 Spinello was painting six frescoes, which still remain on the south wall of the Pisan Campo Santo, representing miracles of St Potitus and St Ephesus. For these he received 270 gold florins. Among his later works the chief are the very fine series of frescoes painted in 1407–1408 on the walls and vault of a chapel in the municipal buildings of Siena; these also have suffered much from repainting, but still are the finest of Spinello's existing frescoes. Sixteen of these represent the war of Frederick Barbarossa against the republic of Venice. Spinello died at Arezzo about 1410.

Spinello's frescoes are all strong and highly decorative works, drawn with much spirit, and are very superior in style to his panel pictures, many of which appear to be mere *bottega* productions. The academy of Florence possesses a panel of the "Madonna and Saints," which is chiefly interesting for its signature—"Hoc opus pinxit Spinellus Luce Aritio D.I.A.(1391)." The easel pictures which are to be found in the various galleries of Europe give little or no notion of Spinello's power as a painter.

SPINET, or SPINNET (Fr. *espinette* or *épinette*; Ger. *Spinett*; Ital. *spinetta*), names given in England to all small keyboard instruments irrespective of shape, having one string to a note, plucked by means of a quill or plectrum of leather. The earliest name recorded for this instrument is clavicymbalum, which occurs in the rules of the Minnesingers (1404), and also in the *Wunderbuch* (1440), a MS. preserved in the grand-ducal library at Weimar. This is enriched with pen and ink sketches, amongst which is a series of musical instruments comprising a clavicymbalum, not represented as the rectangular instrument figured by Virdung and Luscinius, but harp- or wing-shaped like the larger and more perfect instrument afterwards known as harpsichord in England (clavecin, clavicymbel).

In Italy the usual early model of spinet was pentagonal or heptagonal, and was generally enclosed in an outer case, from which it was taken for performance. Some of the oldest rectangular specimens merely contain a pentagonal spinet, the corners not being filled in. In the 16th century the rectangular spinets were modelled in Italy on the *cassone* or wedding coffers, and the keyboard, until the middle of that century, stood out from the case, Rosso of Milan being the first to recess it. Both forms were in use in England until the Restoration, when the transverse or wing form became popular in England, Haward, Stephen Keene and Thomas Hitchcock being the most celebrated English makers[1] at the end of the 17th and beginning of the 18th century.

The mechanism of all spinets, virginals and harpsichords is the same in principle, the principal variation being in the number of strings to each note and the manner in which they are disposed over the soundboard. In the spinets they run parallel or at an obtuse angle to the keyboard. The jack rests on the back of the key-lever, and works through a rectangular hole cut through the soundboard as the key is depressed. The quill or plectrum is embedded in a pivoted tongue near the top of the jack in such a manner that when the tongue is at rest the quill protrudes at right angles just under the string. As the jack rises the quill catches the string and twangs it, causing the tongue, kept in place by a bristle spring, to fall back and thus avoid the string on the return of the jack. A little piece of cloth acting as a damper and attached to the jack rests on the string whenever the key returns to its normal position.

For the history of the spinet, see PIANOFORTE. (K. S.)

[1] See A. J. Hipkins, *The History of the Pianoforte*, pp. 71–73 (London, 1896).

SPINNING (from O. Eng. *spinnan*, to spin, cf. Ger. *spinnen*, &c., the Teut. root is *spen*, to draw out, cf. span, spider), the forming of threads by drawing out and twisting various fibres. There is ample evidence of the great antiquity and wide diffusion of the art of spinning, for spinning necessarily precedes weaving (*q.v.*) whenever short fibrous materials have to be made into threads, and weaving is one of the primal and most universal employments of mankind. Either remains of implements employed in spinning, or spun threads, are found wherever traces of prehistoric man make their appearance. The simple spinning apparatus which was used in the earliest ages continued to be used by civilized communities till comparatively recent times, and it may therefore be said that no art which has been so long and widely practised remained so unprogressive as that of spinning. On the other hand, since about the middle of the 18th century, when human ingenuity bent itself in earnest to improve the art, there have not been developed in the whole range of mechanical industries machines of greater variety, delicacy of action, and manifold productive capacity than those now in use for spinning.

The primitive thread-making implement consisted of a wooden spindle, from 9 to 15 in. long, which was rounded and tapered at both extremities, as in the accompanying figure. Near the

Primitive Spindle.

top there was usually a notch in which the yarn was caught while undergoing the operation of twisting, and lower down a whorl, or wharve, composed of a perforated disk of clay, stone, wood, or other material was secured to give momentum and steadiness to a rotating spindle. Long fibres were commonly attached to a distaff of wood, which was held under the left arm of the operator, but short fibres were spun from carded rolls. After attaching some twisted fibres to the spindle, a rotatory motion was given to the latter either by rolling it by hand against one thigh, or by twirling it between the fingers and thumb of the right hand, after which the fibres were drawn out in a uniform strand by both hands and converted into yarn. When the thread was of sufficient strength, the spindle was suspended by it until a full stretch had been drawn and twisted, after which that portion was wound upon the body of the spindle, and the operation continued until the spindle was filled. The quantity thus rolled up gives the name to a now definite measure of linen yarn, namely "the spindle," or 14,400 yards. Simple as was this primitive apparatus, a dexterous spinner could produce yarn of an evenness, strength and delicacy such as has scarcely been exceeded by elaborate modern appliances. The yarns for the gossamer-like Dacca muslins of India were so fine that 1 lb weight of cotton was spun into a thread nearly 253 m. long. This was accomplished with the aid of a bamboo spindle not much bigger than a darning needle, and which was lightly weighted with a pellet of clay. Since such a tender thread could not support even the weight of so slight a spindle, the apparatus was rotated upon a piece of hollow shell. The spindle as here described was, so far as is known, the sole apparatus with which yarn was spun until comparatively recent times.

The changes in modern spinning have had for their object: (1) the providing of mechanical means to rotate the spindle, (2) an automatic method of drawing out the fibres, and (3) devices for working a large group of spindles together, at speeds before unattainable.

The first improvement consisted in cutting a ring groove in the wharve, mounting the spindle horizontally in a frame, and passing a band from a large wheel round the wharve. A rotatory motion was then given to the spindle by turning the wheel with the left hand. After attaching the filaments to the spindle they were attenuated with the right hand, and when fully twisted the thread was moved to form a right angle with the spindle and coiled upon it. Such a wheel has long been known in India, and from a drawing in a 14th-century manuscript in the British Museum it is obvious that it was not unknown, although far from being in general use, in Europe at that early date. It came ultimately to be known in England as the "bobbing wheel," and was in constant use down to the beginning of the 19th century for spinning coarse and fine yarns. But fine yarns received two spinnings; the first consisted in drawing out and slightly twisting the fibres into what is still known as a roving, and by the second spinning the roving was fully attenuated and twisted. In 1533, a citizen of Brunswick is said to have cranked the axis of the large wheel and added a treadle, by which the spinner was enabled to rotate her spindle with one foot and have both hands free to manipulate the fibres.

It is not possible accurately to fix the dates at which all improvements in spinning appliances were made; it is certain that many were known and used long before they were generally adopted. Thus the flyer, which twists yarn before winding it upon a bobbin, is shown in a drawing by Leonardo da Vinci, together with a device for moving the bobbin up and down the spindle so as to effect an even distribution of the yarn. During the 16th century a machine of the foregoing type was widely used, and came to be known as the Saxony wheel. It changed spinning from an intermittent to a continuous operation. The spindle had affixed upon its outer end a wooden flyer, whose forked legs were far enough apart to enclose a double-flanged spool, and at short intervals bent wires, known as the heck, were inserted in each leg for the purpose of guiding the thread evenly upon the spool. This spool was loosely threaded upon the spindle and one of its flanges was grooved to take a driving band from the large wheel, hence the spindle and the spool were separately driven, but the former at a higher speed than the latter. The twisted filaments were drawn through an eye in the flyer, led along one of its legs, and made fast to the spool. By operating the treadle the flyer twisted all the fibres about a common axis once for each revolution, and the spool wound up the length thus spun: the thread being slipped from tooth to tooth of the heck at regular intervals to direct it evenly across the spool. During the 17th century a second and similar spindle and flyer were added, and these left the spinner free to manipulate one thread with her right, and another with her left hand. It was in this condition that the most advanced form of yarn-making was carried on until a great series of inventions revolutionized spinning, and laid the foundations of the factory system which now prevails.

The remaining part of the problem which lay before inventors was to draw out masses of parallel fibrous material, and twist them into uniform strands by mechanical means. The first stage in the evolution of mechanical spinning was effected by the invention of Lewis Paul, of Birmingham, who obtained a patent in 1738, and who was assisted by John Wyatt. The essential features of this invention consisted in passing carded slivers between pairs of parallel rollers, each succeeding pair of which moved faster than the preceding pair, to attenuate the sliver to the required extent. From Paul's specification it would appear that he attempted to turn the rollers about their horizontal and vertical axes simultaneously, in order to draw out the fibres and twist them at one operation. But he also mentions a plan for which he procured a patent twenty years later, namely, the use of only one pair of rollers working in conjunction with a bobbin which drew off the thread faster than the rollers delivered the sliver, and coiled the thread about itself. The bobbin, therefore, attenuated, twisted and wound the material. Neither plan proved a commercial success. Thomas Highs, of Leigh, and others, laboured upon the problem, but it was left to Richard Arkwright, a barber, of Preston and Bolton, to achieve what his predecessors vainly struggled for. He obtained patents, in 1769 and 1775, for a machine which was subsequently known as the water-twist frame by reason of water-power being applied to drive it. Arkwright's first machine did not contain any really new feature, for it consisted of Paul's drawing rollers, and the spindle, flyer and spool from the Saxony wheel, but the spindles and rollers were grouped in sets of four. Later the water-twist frame was changed into the "throstle" frame, which in turn has almost ceased to be used. In 1829 C. Danforth (1797–1876), an American spinner, invented a dead spindle, on the top of which he placed a hollow cap to serve as the winding point, and inside the cap he rotated a spool: a plan still used by worsted spinners. In 1828 Mr Thorpe, also an American, invented the ring spinning frame, whose principal feature consisted in the substitution for the flyer of a flanged annular ring, and a light C-shaped traveller. By means of the traveller a thread was held in the best position for winding upon a spool, as well as put under the necessary tension. Later inventors have so altered the construction of the ring, traveller and spindle that a speed of upwards of 11,000 revolutions per minute can now be attained. This represents the highest development of continuous spinning.

Whilst endeavours were being made to perfect continuous spinning, attention was also directed to perfecting the intermittent process as represented by the bobbing wheel. Between the years 1764 and 1767, James Hargreaves, of Standhill, invented the spinning jenny, by the aid of which sixteen, or more, threads could be spun simultaneously by one person. All the spindles were placed vertically and rotated from a drum, but the rovings were mounted in a movable carriage and passed between a clamp that opened and shut like a parallel ruler. After securely clamping the rovings and attaching them to the spindles, the carriage was drawn out slowly by one hand and the spindles revolved by the other. The rovings were thus stretched to the proper degree of tenuity, and sufficiently twisted. This was followed by the inward run of the carriage, when the stretch of spun threads was wound upon the spindles, and the operation repeated. Hargreaves therefore returned to the first principles of spinning, namely, simultaneous drawing and twisting. But although the jenny gave a greatly increased output, it was ill adapted for fine spinning. During the years 1774 to 1779, Samuel Crompton, of Bolton, combined, in the mule, the drawing rollers of Paul with the stretching of Hargreaves. But his rollers did not fully attenuate the rovings before twisting them, as is the case with continuous spinning, neither was stretching alone relied upon. From its introduction this machine was able to spin finer and more elastic threads than any of its rivals, but for a time the preparation of suitable rovings was a source of great trouble. The immediate consequence of the decision of the court of King's Bench, in 1785, to throw open to the public Arkwright's preparatory machinery, was to enormously increase the usefulness of the mule. Since Crompton's time a host of inventors have laboured to render all parts of the mule thoroughly automatic; this has led to many changes and additions, but none of its essential features have been discarded. The inventions of Paul, Arkwright, Hargreaves and Crompton are at the foundations of all modern systems of spinning; details regarding them are given in the article on COTTON-SPINNING MACHINERY. (T. W. F.)

SPINOLA, AMBROSE, MARQUIS DE LOS BALBASES (1569–1630), Spanish general, was born in Genoa in 1569. He was the eldest son of Philip Spinola, marquis of Sesto and Benafro, and his wife Policena, daughter of the prince of Salerno. The family of Spinola was of great antiquity, wealth and power in Genoa.

In the 16th century the republic was practically a protected state under the power of Spain, the Genoese being the bankers of the monarchy and having entire control of its finances. Several of the younger brothers of Ambrose Spinola sought their fortune in Spain, and one of them, Frederick, distinguished himself greatly as a soldier in Flanders. The eldest brother remained at home to marry and continue the family. In 1592 he was married to Joanna Bacciadonna, daughter of the count of Galerrata. The houses of Spinola and Doria were rivals for authority within the republic. Ambrose Spinola continued the rivalry with the count of Tursi, then the chief of the Dorias. He was not successful, and having lost a lawsuit into which he had entered to enforce a right of pre-emption of a palace belonging to the Salerno family which the Dorias wished to purchase, he decided to withdraw from the city and advance the fortunes of his house by serving the Spanish monarchy in Flanders. In 1602 he and his brother Frederick entered into a contract with the Spanish government—a "condotta" on the old Italian model. It was a speculation on which Spinola risked the whole of the great fortune of his house. Ambrose Spinola undertook to raise 9000 men for land service, and Frederick to form a squadron of galleys for service on the coast. Several of Frederick's galleys were destroyed by English war-ships on his way up channel. He himself was slain in an action with the Dutch on the 24th of May 1603. Ambrose Spinola marched overland to Flanders in 1602 with the men he had raised at his own expense. During the first months of his stay in Flanders the Spanish government played with schemes for employing him on an invasion of England, which came to nothing. At the close of the year he returned to Italy for more men. His actual experience as a soldier did not begin till as general, and at the age of thirty-four, he undertook to continue the siege of Ostend on the 29th of September 1603. The ruinous remains of the place fell into his hands on the 22nd of September 1604. The archduke Albert and the infanta Clara Eugenia, daughter of Philip II., who then governed Flanders and had set their hearts on taking Ostend, were delighted at his success, and it won him a high reputation among the soldiers of the time. On the close of the campaign he went to Spain to arrange with the court, which was then at Valladolid, for the continuance of the war. At Valladolid he insisted on being appointed commander-in-chief in Flanders. By the 9th of April he was back at Brussels, and entered on his first campaign. The wars of the Low Countries consisted at that time almost wholly of sieges, and Spinola made himself famous by the number of places he took in spite of the efforts of Maurice of Nassau to save them. In 1606 he again went to Spain. He was received with much outward honour, and entrusted with a very secret mission to secure the government of Flanders in case of the death of the archduke or his wife, but he could not obtain the grandeeship which he desired, and was compelled to pledge the whole of his fortune as security for the expenses of the war before the bankers would advance funds to the Spanish government. As he was never repaid, he was in the end utterly ruined. The Spanish government began now to have recourse to devices for keeping him away from Spain. Until the signing of the twelve years' truce in 1609 he continued to command in the field with general success. After it was signed he retained his post, and had among other duties to conduct the negotiations with France when the prince of Condé fled to Flanders with his wife in order to put her beyond the reach of the senile admiration of Henry IV. of France. By 1611 Spinola's financial ruin was complete, but he obtained the desired "grandeza." In 1614 he had some share in the operations connected with the settlement of Cleves and Juliers. On the outbreak of the Thirty Years' War he made a vigorous campaign in the lower Palatinate and was rewarded by the grade of captain-general. After the renewal of the war with Holland in 1621 he gained the most renowned victory of his career—the capture of Breda after a long siege (Aug. 28, 1624–June 5, 1625) and in spite of the most strenuous efforts of the prince of Orange (Frederick Henry) to save it. The surrender of Breda is the subject of the great picture by Velasquez, known as "Las Lanzas"; the portrait of Spinola is from memory.

The taking of Breda was the culmination of Spinola's career. Utter want of money paralysed the Spanish government, and the new favourite, Olivares, was jealous of the general. Spinola could not prevent Frederick Henry of Nassau from taking Groll, a good set-off for Breda. In January 1628 he left for Spain, resolved not to resume the command in Flanders unless security was given him for the support of his army. At Madrid he had to endure much insolence from Olivares, who endeavoured to make him responsible for the loss of Groll. Spinola was resolute not to return to Flanders. Meanwhile the Spanish government added a war over the succession to the duchy of Mantua to its other burdens. Spinola was appointed as plenipotentiary and general. He landed at Genoa on the 19th of September 1629. In Italy he was pursued by the enmity of Olivares, who caused him to be deprived of his powers as plenipotentiary. Spinola's health broke down, and, having been robbed of his money, grudged the compensation he asked for his children and disgraced in the presence of the enemy, he died on the 25th of September 1630 at the siege of Casale, muttering the words "honour" and "reputation." The title of marquis of Los Balbases, still borne by his representatives in Spain, was all that his family received for the vast fortune they spent in the service of Philip III. and IV.

Don A. Rodriguez Villa has published a biography well supplied with original documents—*Ambrosio Spinola, primer marques de los Balbases* (Madrid, 1905). (D. H.)

SPINOLA, CRISTOVAL ROJAS DE (d. 1695), Spanish ecclesiastic, was general of the Franciscan order in Madrid. He went to Vienna as confessor to the Spanish wife of Leopold I., and became bishop of Wienerisch-Neustadt in 1685. He endeavoured to reconcile the Protestant churches with the Roman Catholic, and at a conference at Hanover in 1683 presented his *Regulae circa Christianorum omnium ecclesiasticum reunionem.* The Helmstädt theologians, represented by Gerhard Molanus (1633–1722), at the same time put forward their *Methodus reducendae unionis.* The discussions were approved by the pope and the emperor, but had no popular feeling behind them, and though the negotiations were continued for ten years, especially between Molanus on the one side and Bossuet on the other, no agreement was reached, for the Protestants could not accept the Council of Trent as authoritative or surrender the matter of communion under both species. Spinola died on the 12th of March 1695.

SPINOZA, BARUCH (1632–1677), or, as he afterwards signed himself, Benedict de Spinoza, Dutch philosopher, was born at Amsterdam on the 24th of November 1632. His parents belonged to the community of Jewish emigrants from Portugal and Spain who, fleeing from Catholic persecution in the Peninsula, had sought refuge in the nearly emancipated Netherlands. The name, variously written Espinoza, De Spinoza, D'Espinoza and Despinoza, probably points to the province of Leon as the previous home of the family; there are no fewer than five townships so called in the neighbourhood of Burgos. The philosopher's grandfather appears to have been the recognized head of the Jewish community in Amsterdam in 1628, and his father, Michael Espinoza, was repeatedly warden of the synagogue between 1630 and 1650. The father was a merchant in fair circumstances. He was thrice married and had six children, all of whom predeceased him save a daughter Rebekah, born of the first marriage, and Baruch, the son of his second wife. Spinoza's mother died in 1638 when the boy was barely six years old, and his father in 1654 when he was in his twenty-second year. Spinoza received his first training under the senior rabbi, Saul Levi Morteira, and Manasseh ben Israel, a theological writer of some eminence whose works show considerable knowledge of philosophical authors. Under these teachers he became familiar with the Talmud and, what was probably more important for his own development, with the philosophical writings of Ibn Ezra and Maimonides, Levi ben Gerson, Hasdai Crescas, and other representatives of Jewish medieval thought, who aim at combining the traditional theology with ideas got from Aristotle and his Neoplatonic commentators. Latin, still the universal language of learning, formed no part of Jewish education; and Spinoza, after learning the elements from a German master, resorted for further instruction to a physician named Franz van den Ende, who eked out an income by taking pupils. Van den Ende appears to have been distinctly a man of parts, though of a somewhat indiscreet and erratic character. He was eventually hanged in Paris as a conspirator in 1674. His enthusiasm for the natural sciences may have been the only ground for the reputation he had acquired of instilling atheistic notions into the minds of his pupils along with the Latin which he taught them. But it is quite possible that his scientific studies had bred in him, as in many others at that time, a materialistic, or at least a naturalistic, turn of mind; indeed, we should expect as much in a man of Van den Ende's somewhat rebellious temperament. We do not know whether his influence was brought to bear in this sense upon Spinoza; but it has been suggested that the writings of Bruno, whose spirit of enthusiastic naturalism and fervid revolt against the Church would be especially dear to a man of Van den Ende's leanings, may have been put into the pupil's hand by the master. Latin, at all events, Spinoza learned to use with correctness, freedom and force, though his language does not, of course, conform to classical canons.

A romance has woven itself round Spinoza's connexion with Van den Ende's household. The physician had an only daughter, Clara Maria by name, who, besides being proficient in music, understood Latin, it is said, so perfectly that she was able to teach her father's pupils in his absence. Spinoza, the story goes, fell in love with his fair instructress; but a fellow-student, called Kerkering, supplanted him in his mistress's affections by the help of a valuable necklace of pearls which he presented to the young lady. Chronology unfortunately forbids us to accept this little episode as true. Recent investigation has proved that, while the marriage with Kerkering, or rather Kerckkrink, is a fact, it did not take place till 1671, in which year the bride, as appears by the register, was twenty-seven years of age. She cannot, therefore, have been more than eleven, or twelve in 1656, the year in which Spinoza left Amsterdam; and as Kerckkrink was seven years younger than Spinoza, they cannot well have been simultaneous pupils of Van den Ende's and simultaneous suitors for his daughter's hand. But, though the details of the story thus fall to pieces, it is still possible that in the five years which followed his retirement from Amsterdam Spinoza, who was living within easy distance and paid visits to the city from time to time, may have kept up his connexion with Van den Ende, and that the attachment may have dated from this later period. This would at least be some explanation for the existence of the story; for Colerus expressly says that Spinoza "often confessed that he meant to marry her." But there is no mention of the Van den Endes in Spinoza's correspondence; and in the whole tenor of his life and character there is nothing on which to fasten the probability of a romantic attachment.

The mastery of Latin which he acquired from Van den Ende opened up to Spinoza the whole world of modern philosophy and science, both represented at that time by the writings of Descartes. He read him greedily, says Colerus, and afterwards often declared that he had all his philosophical knowledge from him. The impulse towards natural science which he had received from Van den Ende would be strengthened by the reading of Descartes; he gave over divinity, we are told, to devote himself entirely to these new studies. His inward break with Jewish orthodoxy dated, no doubt, further back—from his acquaintance with the philosophical theologians and commentators of the middle ages; but these new interests combined to estrange him still further from the traditions of the synagogue. He was seldomer seen at its services—soon not at all. The jealousy of the heads of the synagogue was easily roused. An attempt seems to have been made to draw from him his real opinions on certain prominent points of divinity. Two so-called friends endeavoured, on the plea of doubts of their own, to lead him into a theological discussion; and, some of Spinoza's expressions being repeated to the Jewish authorities, he was summoned to give an account of himself. Anxious to retain so promising an adherent, and probably desirous at the same time to avoid public scandal, the chiefs of the community offered him a yearly pension of 1000 florins if he would outwardly conform and appear now and then in the synagogue. But such deliberate hypocrisy was abhorrent to Spinoza's nature. Threats were equally unavailing, and accordingly on the 27th of July 1656 Spinoza was solemnly cut off from the commonwealth of Israel. The curses pronounced against him may be read in most of the biographies. While negotiations were still pending, he had been set upon one evening by a fanatical ruffian, who thought to expedite matters with the dagger. Warned by this that Amsterdam was hardly a safe place of residence for him any longer, Spinoza had already left the city before the sentence of excommunication was pronounced. He did not go far, but took up his abode with a friend who lived some miles out on the Old Church road. His host belonged to the Collegiants or Rhijnsburgers, a religious society which had sprung up among the proscribed Arminians of Holland. The pure morality and simple-minded piety of this community seem early to have attracted Spinoza, and to have won his unfeigned respect. Several of his friends were Collegiants, or belonged to the similarly minded community of the Mennonites, in which the Collegiants were afterwards merged. In this quiet retreat Spinoza spent nearly five years. He drew up a protest against the decree of excommunication, but otherwise it left him unmoved. From this time forward he disused his Hebrew name of Baruch, adopting instead the Latin equivalent, Benedictus. Like every Jew, Spinoza had learned a handicraft; he was a grinder of lenses for optical instruments, and was thus enabled to earn an income sufficient for his modest wants. His skill, indeed, was such that lenses of his making were much sought after, and those found in his cabinet after his death fetched a high price. It was as an optician that he was first brought into connexion with Huygens and Leibnitz; and an optical *Treatise on the Rainbow*, written by him and long supposed to be lost, was discovered and reprinted by Dr Van Vloten in 1862. He was also fond of drawing as an amusement in his leisure hours; and Colerus had seen a sketch-book full of such drawings representing persons of Spinoza's acquaintance, one of them being a likeness of himself in the character of Masaniello.

The five years which followed the excommunication must have been devoted to concentrated thought and study. Before their conclusion Spinoza had parted company from Descartes, and the leading positions of his own system were already clearly determined in his mind. A number of the younger men in Amsterdam—many of them students of medicine or medical practitioners—had also come to regard him as their intellectual leader. A kind of philosophical club had been formed, including among its members Simon de Vries, John Bresser, Louis Meyer, and others who appear in Spinoza's correspondence. Originally meeting in all probability for more thoroughgoing study of the Cartesian philosophy, they looked naturally to Spinoza for guidance, and by and by we find him communicating systematic drafts of his own views to the little band of friends and students. The manuscript was read aloud and discussed at their meetings, and any points remaining obscure were referred to Spinoza for further explanation. An interesting specimen of such difficulties propounded by Simon de Vries and resolved by Spinoza in accordance with his own principles, is preserved for us in Spinoza's correspondence. This Simon de Vries was a youth of generous impulses and of much promise. Being in good circumstances, he was anxious to show his gratitude to Spinoza by a gift of 2000 florins, which the philosopher half-jestingly excused himself from accepting. De Vries died young, and would fain have left his fortune to Spinoza; but the latter refused to stand in the way of his brother, the natural heir, to whom the property was accordingly left, with the condition that he should pay to Spinoza an annuity sufficient for his maintenance. The heir offered to fix the amount at 500 florins, but Spinoza accepted only 300, a sum which was regularly paid till his death. The written communications of his own doctrine referred to above belong to a period after Spinoza had removed from the neighbourhood of Amsterdam; but it has been conjectured that the *Short Treatise on God, on Man, and his Wellbeing*, which represents his thoughts in their earliest systematic form, was left by him as a parting legacy to this group of friends. It is at least certain, from a reference in Spinoza's first letter to Oldenburg, that such a systematic exposition was in existence before September 1661.[1] There are two dialogues somewhat loosely incorporated with the work which probably belong to a still earlier period. The short appendix, in which the attempt is made to present the chief points of the argument in geometrical form, is a forerunner of the *Ethics*, and was probably written somewhat later than the rest of the book. The term "Nature" is put more into the foreground in the *Treatise*, a point which might be urged as evidence of Bruno's influence—the dialogues, moreover, being specially concerned to establish the unity, infinity and self-containedness of Nature[2]; but the two opposed Cartesian attributes, thought and extension, and the absolutely infinite substance whose attributes they are—substance constituted by infinite attributes—appear here as in the *Ethics*. The latter notion—of substance—is said to correspond exactly to "the essence of the only glorious and blessed God." The earlier differs from the later exposition in allowing an objective causal relation between thought and extension, for which there is substituted in the *Ethics* the idea of a thoroughgoing parallelism. The *Short Treatise* is of much interest to the student of Spinoza's philosophical development, for it represents, as Martineau says, "the first landing-place of his mind in its independent advance." Although the systematic framework of the thought and the terminology used are both derived from the Cartesian philosophy, the intellectual *milieu* of the time, the early work enables us, better than the *Ethics* to realize that the inspiration and starting-point of his thinking is to be found in the religious speculations of his Jewish predecessors. The histories of philosophy may quite correctly describe his theory as the logical development of Descartes's doctrines of the one Infinite and the two finite substances, but Spinoza himself was never a Cartesian. He brought his pantheism and his determinism with him to the study of Descartes from the mystical theologians of his race.

Early in 1661 Spinoza's host removed to Rhijnsburg near Leiden, the headquarters of the Collegiant brotherhood, and Spinoza removed with him. The house where they lived at Rhijnsburg is still standing, and the road bears the name of Spinoza Lane. Very soon after his settlement in his new quarters he was sought out by Henry Oldenburg, the first secretary of the Royal Society.[3] Oldenburg became Spinoza's most regular correspondent—a third of the letters preserved to us are to or from him; and it appears from his first letter that their talk on this occasion was "on God, on infinite extension and thought, on the difference and the agreement of these attributes, on the nature of the union of the human soul with the body, as well as concerning the principles of the Cartesian and Baconian philosophies." Spinoza must, therefore, have unbosomed himself pretty freely to his visitor on the main points of his system. Oldenburg, however, was a man of no speculative capacity, and, to judge from his subsequent correspondence, must have quite failed to grasp the real import and scope of the thoughts communicated to him. From one of Oldenburg's early letters we learn that the treatise *De intellectus emendatione* was probably Spinoza's first occupation at Rhijnsburg. The nature of the work also bears out the supposition that it was first undertaken. It is, in a manner, Spinoza's "organon"—the doctrine of method which he would substitute for the corresponding doctrines of Bacon and Descartes as alone consonant with the thoughts which were shaping themselves or had shaped themselves in his mind. It is a theory of philosophical truth and error, involving an account of the course of philosophical inquiry and of the supreme object of knowledge. It was apparently intended by the author as an analytical introduction to the constructive exposition of his system, which he presently essayed in the *Ethics*. But he must have found as he proceeded that the two treatises would cover to a large extent the same ground, the account of the true method merging almost inevitably in a statement of the truth reached by its means. The *Improvement of the Understanding* was therefore put aside unfinished, and was first published in the *Opera posthuma*. Spinoza meanwhile concentrated his attention upon the *Ethics*, and we learn from the correspondence with his Amsterdam friends that a considerable part of book i. had been communicated to the philosophical club there before February 1663. It formed his main occupation for two or three years after this date. Though thus giving his friends freely of his best, Spinoza did not cast his thoughts broadcast upon any soil. He had a pupil living with him at Rhijnsburg whose character seemed to him lacking in solidity and discretion. This pupil (probably Albert Burgh, who afterwards joined the Church of Rome and penned a foolishly insolent epistle to his former teacher) was the occasion of Spinoza's first publication—the only publication indeed to which his name was attached. Not deeming it prudent to initiate the young man into his own system, he took for a textbook the second and third parts of Descartes's *Principles*, which deal in the main with natural philosophy. As he proceeded he put Descartes's matter in his own language and cast the whole argument into a geometric form. At the request of his friends he devoted a fortnight to applying the same method to the first or metaphysical part of Descartes's philosophy, and the sketch was published in 1663, with an appendix entitled *Cogitata metaphysica*, still written from a Cartesian standpoint (defending, for example, the freedom of the will), but containing hints of his own doctrine. The book was revised by Dr Meyer for publication and furnished by him, at Spinoza's request, with a preface in which it is expressly stated that the author speaks throughout not in his own person but simply as the exponent of Descartes. A Dutch translation appeared in the following year.[4]

In 1663 Spinoza removed from Rhijnsburg to Voorburg, a suburban village about 2 m. from the Hague. His reputation had continued to spread. From Rhijnsburg he had paid frequent visits to the Hague, and it was probably the desire

[1] Various manuscript copies were apparently made of the treatise in question, but it was not printed, and dropped entirely out of knowledge till 1852, when Edward Böhmer of Halle lighted upon an abstract of it attached to a copy of Colerus's *Life*, and shortly afterwards upon a Dutch MS. purporting to be a translation of the treatise from the Latin original. This was published in 1862 by Van Vloten with a retranslation into Latin. Since then a superior Dutch translation has been discovered, which has been edited by Professor Schaarschmidt and translated into German. Another German version with introduction and notes has been published by Sigwart based on a comparison of the two Dutch MSS. A scholarly English translation similarly equipped was published by A. Wolf in 1910.

[2] The fact that Spinoza nowhere mentions Bruno would not imply, according to the literary habits of those days, that he was not acquainted with his speculations and even indebted to them. There is no mention, for example, of Hobbes throughout Spinoza's political writing, and only one casual reference to him in a letter, although the obligation of the Dutch to the English thinker lies on the surface. Accordingly, full weight must be allowed to the internal evidence brought forward by Sigwart, Avenarius and others to prove Spinoza's acquaintance with Bruno's writings. But the point remains quite doubtful and is in any case of little importance.

[3] Heinrich Oldenburg (*c.* 1626–1678) was a native of Bremen, but had settled in England in the time of the commonwealth. Though hardly a scientific man himself, he had a genuine interest in science, and must have possessed social gifts. He was the friend of Boyle, and acquainted with most of the leaders of science in England as well as with many on the Continent. He delighted to keep himself in this way *au courant* with the latest developments, and lost no opportunity of establishing relations with men of scientific reputation. It was probably at the suggestion of Huygens that he bent his steps towards Spinoza's lodging.

[4] The title of the Latin original ran—*Renati des Cartes principiorum philosophiae pars i. et ii. more geometrico demonstratae per Benedictum de Spinoza Amstelodamensem. Accesserunt ejusdem cogitata metaphysica.*

to be within reach of some of the friends he had made in these visits—among others the De Witts—that prompted his changed residence. He had works in hand, moreover, which he wished in due time to publish; and in that connexion the friendly patronage of the De Witts might be of essential service to him. The first years at Voorburg continued to be occupied by the composition of the *Ethics*, which was probably finished, however, by the summer of 1665. A journey made to Amsterdam in that year is conjectured to have had reference to its publication. But, finding that it would be impossible to keep the authorship secret, owing to the numerous hands through which parts of the book had already passed, Spinoza determined to keep his manuscript in his desk for the present. In September 1665 we find Oldenburg twitting him with having turned from philosophy to theology and busying himself with angels, prophecy and miracles. This is the first reference to the *Tractatus theologico-politicus*, which formed his chief occupation for the next four years. The aim of this treatise may be best understood from the full title with which it was furnished—*Tractatus theologico-politicus, continens dissertationes aliquot, quibus ostenditur libertatem philosophandi non tantum salva pietate et reipublicae pace posse concedi sed eandem nisi cum pace reipublicae ipsaque pietate tolli non posse.* It is, in fact, an eloquently reasoned defence of liberty of thought and speech in speculative matters. The external side of religion—its rites and observances—must of necessity be subject to a certain control on the part of the state, whose business it is to see to the preservation of decency and order. But, with such obvious exceptions, Spinoza claims complete freedom of expression for thought and belief; and he claims it in the interests alike of true piety and of the state itself. The thesis is less interesting to a modern reader—because now generally acknowledged—than the argument by which it is supported. Spinoza's position is based upon the thoroughgoing distinction drawn in the book between philosophy, which has to do with knowledge and opinion, and theology, or, as we should now say, religion, which has to do exclusively with obedience and conduct. The aegis of religion, therefore, cannot be employed to cover with its authority any speculative doctrine; nor, on the other hand, can any speculative or scientific investigation be regarded as putting religion in jeopardy. Spinoza undertakes to prove his case by the instance of the Hebrew Scriptures. Scripture deals, he maintains, in none but the simplest precepts, nor does it aim at anything beyond the obedient mind; it tells nought of the divine nature but what men may profitably apply to their lives. The greater part of the treatise is devoted to working out this line of thought; and in so doing Spinoza consistently applies to the interpretation of the Old Testament those canons of historical exegesis which are often regarded as of comparatively recent growth. The treatise thus constitutes the first document in the modern science of Biblical criticism. It was published in 1670, anonymously, printer and place of publication being likewise disguised (*Hamburgi apud Heinricum Künraht*). The storm of opposition which it encountered showed that these precautions were not out of place. It was synodically condemned along with Hobbes's *Leviathan* and other books as early as April 1671, and was consequently interdicted by the states-general of Holland in 1674; before long it was also placed on the *Index* by the Catholic authorities. But that it was widely read appears from its frequent reissue with false title-pages, representing it now as an historical work and again as a medical treatise. Controversialists also crowded into the lists against it. A translation into Dutch appears to have been proposed; but Spinoza, who foresaw that such a step would only increase the commotion which was so distasteful to him, steadily set his face against it. No Dutch translation appeared till 1693.

The same year in which the *Tractatus* was published Spinoza removed from his suburban lodging at Voorburg into the Hague itself. He took rooms first on the Veerkay with the widow Van de Velde, who in her youth had assisted Grotius to escape from his captivity at Loewenstein. This was the house afterwards occupied by Colerus, the worthy Lutheran minister who became Spinoza's biographer. But the widow insisted on boarding her lodger, and Spinoza presently found the expense too great for his slender purse. He accordingly removed to a house on the Pavelioen Gracht near at hand, occupied by a painter called Van der Spijck. Here he spent the remaining years of his life in the frugal independence which he prized. Colerus gives particulars which enable us to realize the almost incredible simplicity and economy of his mode of life. He would say sometimes to the people of the house that he was like the serpent which forms a circle with its tail in its mouth, meaning thereby that he had nothing left at the year's end. His friends came to visit him in his lodgings, as well as others attracted by his reputation—Leibnitz among the rest—and were courteously entertained, but Spinoza preferred not to accept their offers of hospitality. He spent the greater part of his time quietly in his own chamber, often having his meals brought there and sometimes not leaving it for two or three days together when absorbed in his studies. On one occasion he did not leave the house for three months. "When he happened to be tired by having applied himself too much to his philosophical meditations, he would go downstairs to refresh himself, and discoursed with the Van der Spijcks about anything that might afford matter for an ordinary conversation, and even about trifles. He also took pleasure in smoking a pipe of tobacco; or, when he had a mind to divert himself somewhat longer, he looked for some spiders and made them fight together, or he threw some flies into the cobweb, and was so well pleased with the result of that battle that he would sometimes break into laughter" (Colerus). He also conversed at times on more serious topics with the simple people with whom he lodged, often, for example, talking over the sermon with them when they came from church. He occasionally went himself to hear the Lutheran pastor preach—the predecessor of Colerus—and would advise the Van der Spijcks not to miss any sermon of so excellent a preacher. The children, too, he put in mind of going often to church, and taught them to be obedient and dutiful to their parents. One day his landlady, who may have heard strange stories of her solitary lodger, came to him in some trouble to ask him whether he believed she could be saved in the religion she professed. "Your religion is a good one," said Spinoza; "you need not look for another, nor doubt that you will be saved in it, provided that, while you apply yourself to piety, you live at the same time a peaceable and quiet life." Only once, it is recorded, did Spinoza's admirable self-control give way, and that was when he received the news of the murder of the De Witts by a frantic mob in the streets of the Hague. It was in the year 1672, when the sudden invasion of the Low Countries by Louis XIV. raised an irresistible clamour for a military leader and overthrew the republican constitution for which the De Witts had struggled. John De Witt had been Spinoza's friend, and had bestowed a small pension upon him; he had Spinoza's full sympathy in his political aims. On receiving the news of the brutal murder of the two brothers, Spinoza burst into tears, and his indignation was so roused that he was bent upon publicly denouncing the crime upon the spot where it had been committed. But the timely caution of his host prevented his issuing forth to almost certain death. Not long after Spinoza was himself in danger from the mob, in consequence of a visit which he paid to the French camp. He had been in correspondence with one Colonel Stoupe, a Swiss theologian and soldier, then serving with the prince of Condé, the commander of the French army at Utrecht. From him Spinoza received a communication enclosing a passport from the French commander, who wished to make his acquaintance and promised him a pension from the French king at the easy price of a dedication to his majesty. Spinoza went to Utrecht, but returned without seeing Condé, who had in the meantime been called elsewhere; the pension he civilly declined. There may have been nothing more in the visit than is contained in this narrative; but on his return Spinoza found that the populace of the Hague regarded him as no better than a spy. The town was full of angry murmurs, and the landlord feared that the mob would storm his house and drag Spinoza out. Spinoza quieted his fears as well as he could, assuring him that as soon as the crowd made any threatening movement he would go out to meet them, "though they should serve me as they did the poor De Witts. I am a good republican and have never had any aim but the honour and welfare of the state." Happily the danger passed off without calling for such an ordeal.

In 1673 Spinoza received an invitation from the elector palatine to quit his retirement and become professor of philosophy in the university of Heidelberg. The offer was couched in flattering terms, and conveyed an express assurance of "the largest freedom of speech in philosophy, which the prince is confident that you will not misuse to disturb the established religion." But Spinoza's experience of theological sensitiveness led him to doubt the possibility of keeping on friendly terms with the established religion, if he were placed in a public capacity. Moreover, he was not strong; he had had no experience of public teaching; and he foresaw that the duties of a chair would put an end to private research. For all these reasons he courteously declined the offer made to him. There is little more to tell of his life of solitary meditation. In 1675 we learn from his correspondence that he entertained the idea of publishing the *Ethics*, and made a journey to Amsterdam to arrange matters with the printer. "But, whilst I was busy with this," he writes, "the report was spread everywhere that a certain book of mine was in the press, wherein I endeavoured to show that there was no God; and this report found credence with many. Whereupon certain theologians (themselves perhaps the authors of it) took occasion to complain of me to the prince and the magistrates; moreover, the stupid Cartesians, because they are commonly supposed to side with me, desiring to free themselves from that suspicion, were diligent without ceasing in their execrations of my doctrines and writings, and are as diligent still." As the commotion seemed to grow worse instead of subsiding, Spinoza consigned the manuscript once more to his desk, from which it was not to issue till after his death. His last literary work was the unfinished *Tractatus politicus* and the preparation of notes for a new edition of the *Tractatus theologico-politicus*, in which he hoped to remove some of the misunderstandings which the book had met with. The *Tractatus politicus* develops his philosophy of law and government on the lines indicated in his other works, and connects itself closely with the theory enunciated by Hobbes a generation before. Consumption had been making its insidious inroads upon Spinoza for many years, and early in 1677 he must have been conscious that he was seriously ill. On Saturday, the 20th of February, he sent to Amsterdam for his friend Dr Meyer. On the following day, the Van der Spijcks, having no thought of immediate danger, went to the afternoon service. When they came back Spinoza was no more; he had died about three in the afternoon with Meyer as the only witness of his last moments. Spinoza was buried on the 25th of February "in the new church upon the Spuy, being attended," Colerus tells us, "by many illustrious persons and followed by six coaches." He was little more than forty-four years of age.

Spinoza's effects were few and realized little more than was required for the payment of charges and outstanding debts. "One need only cast one's eyes upon the account," says his biographer, "to perceive that it was the inventory of a true philosopher. It contains only some small books, some engravings, a few lenses and the instruments to polish them." His desk, containing his letters and his unpublished works, Spinoza had previously charged his landlord to convey to Jan Rieuwertz, a publisher in Amsterdam. This was done, and the *Opera posthuma* appeared in the same year, without the author's name, but with his initials upon the title-page. They were furnished with a preface written in Dutch by Jarig Jellis, a Mennonite friend of Spinoza's, and translated into Latin by Dr Meyer. Next year the book was proscribed in a violently worded edict by the states of Holland and West Friesland. The obloquy which thus gathered round Spinoza in the later years of his life remained settled upon his memory for a full hundred years after his death. Hume's casual allusion to "this famous atheist" and his "hideous hypothesis" is a fair specimen of the tone in which he is usually referred to; people talked about Spinoza, Lessing said, "as if he were a dead dog." The change of opinion in this respect may be dated from Lessing's famous conversation with Jacobi in 1780. Lessing, Goethe, Herder, Novalis and Schleiermacher, not to mention philosophers like Schelling and Hegel, united in recognizing the unique strength and sincerity of Spinoza's thought, and in setting him in his rightful place among the speculative leaders of mankind. Transfused into their writings, his spirit has had a large share in moulding the philosophic thought of the 19th century, and it has also been widely influential beyond the schools. Instead of his atheism Hegel speaks of his acosmism, and Novalis dubs him a God-intoxicated man. Schleiermacher's fine apostrophe is well known, in which he calls upon us to "offer a lock of hair to the manes of the holy and excommunicated Spinoza."

Spinoza's personal appearance is described by Colerus from the accounts given him by many people at the Hague who knew him familiarly. "He was of a middle size, and had good features in his face, the skin somewhat dark, black curled hair, and the long eyebrows of the same colour, so that one might easily know from his looks that he was descended from the Portuguese Jews." Leibnitz also gives a similar description: "The celebrated Jew Spinoza had an olive complexion and something Spanish in his face." These characteristics are preserved in a portrait in oil in the Wolfenbüttel library, which was probably the original of the (in that case unsuccessfully rendered) engraving prefixed to the *Opera posthuma* of 1677. This portrait was photographed for Dr Martineau's *Study of Spinoza*. In 1880 a statue was erected to Spinoza at the Hague by international subscription among his admirers, and more recently the cottage in which he lived at Rhijnsburg has been restored and furnished with all the discoverable Spinoza relics.

Spinoza's philosophy is a thoroughgoing pantheism, which has both a naturalistic and a mystical side. The foundation of the system is the doctrine of one infinite substance, of which all finite existences are modes or limitations (modes of thought or modes of extension). God is thus the immanent cause of the universe; but of creation or will there can be no question in Spinoza's system. God is used throughout as equivalent to Nature (*Deus sive natura*). The philosophical standpoint comprehends the necessity of all that is—a necessity that is none other than the necessity of the divine nature itself. To view things thus is to view them, according to Spinoza's favourite phrase, *sub specie aeternitatis*. Spinoza's philosophy is fully considered in the article CARTESIANISM.

LITERATURE.—The contents of the *Opera posthuma* included the *Ethics*, the *Tractatus politicus* and the *De intellectus emendatione* (the last two unfinished), a selection from Spinoza's correspondence, and a *Compendium of Hebrew Grammar*. The *Treatise on the Rainbow*, supposed to be lost, was published anonymously in Dutch in 1687. The first collected edition of Spinoza's works was made by Paulus in 1802; there is another by Gfrörer (1830), and a third by Bruder (1843–1846) in three volumes. Van Vloten's volume, published in 1862, *Ad Benedicti de Spinoza opera quae supersunt omnia supplementum*, is uniform with Bruder's edition, and contains the early treatise *De deo et homine*, the *Treatise on the Rainbow*, and several fresh letters. A complete edition undertaken by Dr Van Vloten and Professor J. P. N. Land for the Spinoza Memorial Committee formed in Holland to celebrate the bicentenary of the philosopher's death appeared in 1882 and was reissued in three volumes in 1895. An English translation of *The Chief Works of Spinoza*, by R. H. M. Elwes, appeared in 1883, and translations of the *Ethics* and the *De intellectus emendatione* were published in 1883 and 1895 by W. Hale White; A. Wolf's translation of the *Short Treatise* appeared in 1910; previous translations were unscholarly in execution.

The main authority for Spinoza's life is the sketch published in 1705, in Dutch, with a controversial sermon against Spinozism, by Johannes Colerus. The French version of this *Life* (1706) has been several times reprinted as well as translated into English and German. The English version, also dating from 1706, was reprinted by Sir Frederick Pollock at the end of his *Spinoza, his Life and Philosophy* (1880). This book, Dr Martineau's *Study of Spinoza* (1882) and Dr John Caird's *Spinoza* (1888), are all admirable pieces of work, and, as regards the philosophical estimate, complement one another. H. H. Joachim's *Study of the Ethics of Spinoza* (1901) and R. A. Duff's *Spinoza's Political and Ethical Philosophy* (1903) are important contributions of more recent date. Careful research by Professor Freudenthal, Dr W. Meyer and Dr K. O. Meinsma has recently brought to light a number of fresh details connected with Spinoza's life and increased our knowledge of his Jewish and Dutch environment. The earliest lives and all the available documents have been edited by Freudenthal in a single volume, *Die Lebensgeschichte Spinozas* (1899), on the basis of which he has since rewritten the Life, *Spinozas Leben und Lehre*, vol. i., *Das Leben* (1904). Meinsma's *Spinoza und en zijn Kring* (1896) appeared in a German translation in 1909. The new material has been judicially used by A. Wolf in the "Life" prefixed to his translation of the *Short Treatise* (1910), and the greater part of it also in the second edition of Sir Frederick Pollock's *Spinoza* (1899). (A. S. P.-P.)

SPINY SQUIRREL, a book-name for a group of African ground squirrels, characterized by the spiny nature of the fur of the more typical forms. They form the genus *Xerus*, which is split up into a number of subgenera; *Xerus rutilus* of Abyssinia and East Africa belonging to the typical group, while the striped

North African *X. getulus* represents the sub-genus *Atlantoxerus*. The more typical species are characterized by the coarse spiny hair, the small size, or even absence of the ears, and the long, nearly straight, claws. The skull is narrower and longer than in typical squirrels, and there are distinctive features in the cheek-teeth; but the more aberrant types come much closer to squirrels. Typical spiny squirrels differ from true squirrels in being completely terrestrial in their habits, and live either in clefts or holes of rocks, or in burrows which they dig themselves. (See RODENTIA.)

SPION KOP, a mountain in Natal on the north side of the Tugela River, and 24 m. W.S.W. of Ladysmith. It is celebrated as the scene of a battle (Jan. 24, 1900) in the Transvaal War, in which the British forces under Sir Redvers Buller were defeated by the Boers (see TRANSVAAL and LADYSMITH). The Spion Kop incident led to much controversy; for an admirable elucidation of the facts see *The Times History of the War in South Africa*. The name itself (Dutch for "Look-out Hill") is fairly common as a place-name in South Africa.

SPIRAL, in mathematics, the locus of the extremity of a line (or radius vector) which varies in length as it revolves about a fixed point (or origin). Here we consider some of the more important plane spirals. Obviously such curves are conveniently expressed by polar equations, *i.e.* equations which directly state a relation existing between the radius vector and the vector angle; another form is the "p, r" equation, wherein r is the radius vector of a point, and p the length of the perpendicular from the origin to the tangent at that point.

The equiangular or logarithmic spiral (fig. 1) is such that as the vector angle increases arithmetically, the radius vector increases

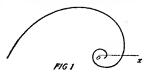


FIG 1

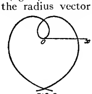

FIG 2.

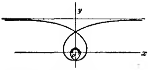

FIG 3.

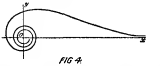

FIG 4.

geometrically; this definition leads to an equation of the form $r = Ae^{B\theta}$, where e is the base of natural logarithms and A, B are constants. Another definition is that the tangent makes a constant angle (α, say) with the radius vector; this leads to $p = r \sin \alpha$. This curve has the property that its positive pedals, inverse, polar reciprocal and evolutes are all equal equiangular spirals. A group of spirals are included in the "parabolic spirals" given by the equation $r = a\theta^n$; the more important are the Archimedean spiral, $r = a\theta$ (fig. 2); the hyperbolic or reciprocal spiral, $r = a\theta^{-1}$ (fig. 3); and the lituus, $r = a\theta^{-\frac{1}{2}}$ (fig. 4). The first-named was discovered by Conon, whose studies were completed by Archimedes. Its "p, r" equation is $p = r^2/\sqrt{(a^2+r^2)}$, and the angle between the radius vector and the tangent equals the vector angle. The second, called hyperbolic on account of the analogy of its equation (polar) to that (Cartesian) of a hyperbola between the asymptotes, is the inverse of the Archimedean. Its p, r equation is $p^{-2} = r^{-2} + a^{-2}$, and it has an asymptote at the distance a above the initial line. The lituus has the initial line as asymptote. Another group of spirals—termed Cotes's spirals—appear as the path of a particle moving under the influence of a central force varying as the inverse cube of the distance (see MECHANICS). Their general equation is $p^{-2} = Ar^{-2} + B$, in which A and B can have any values. If $B = 0$, we have $p = r\sqrt{A}$, and the locus is the equiangular spiral. If $A = 1$ we have $p^{-2} = r^{-2} + B$, which leads to the polar equation $r\theta = 1/\sqrt{B}$, *i.e.* the reciprocal spiral. The more general investigation is as follows: Writing $u = r^{-1}$ we have $p^{-2} = Au^2 + B$, and since $p^{-2} = u^2 + (du/d\theta)^2$ (see INFINITESIMAL CALCULUS), then $Au^2 + B = u^2 + (du/d\theta)^2$, *i.e.* $(du/d\theta)^2 = (A-1)u^2 + B$. The right-hand side may be written as $C^2(u^2 + D^2)$, $C^2(u^2 - D^2)$, $C^2(D^2 - u^2)$ according as $A - 1$ and B are both positive, $A - 1$ positive and B negative, and as $A - 1$ negative and B positive. On integration these three forms yield the polar equations $u = C \sin hD\theta$, $u = C \cos hD\theta$, and $u = C \sin D\theta$. Of interest is the spiral $r = a\theta^2/(\theta^2 - 1)$, which has the circle $r = a$ as an asymptote in addition to a linear asymptote

SPIRE (O. Eng. *spir*, a blade of grass, and so anything tapering to a point), the architectural term (Fr. *flèche*, Ital. *guglia*, Ger. *spitze*) given to the lofty roofs in stone or wood covered with lead or slate, which crown the towers of cathedrals, churches, &c. In their origin, as in the church of Thaon in Normandy, they were four-sided roofs of slight elevation, but soon began to be features of great importance, becoming lofty pyramids generally of octagonal form, and equal in height sometimes to the towers themselves. The junction, however, of an octagonal spire and a square tower involved a distinct architectural problem, and its solutions in English, French and German spires are of infinite variety. One of the earliest treatments is that of the south-west tower of Chartres Cathedral, where, on the four projecting angles are lofty spire lights which, with others on the four faces and the octagonal spire itself, form a fine composition; at the abbey of St Denis the spire light at each angle was carried on three columns which filled better the three-cornered space at the angles and gave greater lightness to the structure; long vertical slits in the spire lights and the spire increased this effect, leading eventually to the introduction of tracery throughout the spire; the ultimate results of this we see in the lace-work spires of Strassburg, Antwerp, St Stephen's at Vienna, Freiberg, Ulm and other examples, which in some cases must be looked upon as the *tours de force* of the masons employed. In England the spires were far less pretentious but of greater variety of form. The spire of the cathedral at Oxford (1220) is perhaps the earliest example; it is of comparatively low elevation, of octagonal form with marked entasis, and is decorated with spire lights on each face and pinnacled turrets at the angles. Those which are peculiar to England are the broach-spires, in which the four angles of the tower are covered with a stone roof which penetrates the central, octagonal spire. In the best examples the spire comes down on the tower with dripping eaves, and is carried on a corbel table, of which the finest solution is St Mary's at Stamford. The angles of the octagonal spire have a projecting moulding which is stopped by a head just above the corbel table, and at the top of the broach is a small niche with a figure in it; the spire lights are in three stages alternately in the front and diagonal faces. At St Mary, Kelton, and St Nicholas, Walcot, are similar designs. Seen, however, on the diagonal, the void space at the angles of these broach-spires is noticeable, so that an octagonal pinnacle was erected, of which the earliest example is that of the cathedral at Oxford, where the broach was of very low pitch. Of later date St Mary's, Wollaston, All Saints, Leighton Buzzard, and St Mary's, Witney, are good examples. As a rule the broach penetrates the octagonal spire about one-sixth or one-seventh up its height, but there is one instance in St Nicholas, Cotsmere, in Rutlandshire, where it rises nearly half the way up the octagonal spire. When the parapet or battlement (the latter being purely decorative) took the place of the dripping eaves, the broach disappeared, and octagonal turrets occupy the corners, as in St Peter's at Kettering and Oundle, Northamptonshire, and in All Saints, Stamford, Lincolnshire. The next combination perhaps followed from this; in order to connect the angle tower or pinnacle with the spire, a flying buttress was thrown across, thus filling the gap between them; of this St James's, at Louth, in Lincolnshire, may be taken as a fine type; it belongs to the Perpendicular period and is further enriched with crockets up each angle of the spire; the same is found in St Mary's, Whittlesea, Cambridgeshire. At St Michael's, Coventry, the lower part of the octagonal spire is made vertical with a battlemented cresting round it. In St Patrick's, Partington, Yorkshire, the lower part of the spire, which otherwise is plain, is enclosed with an open gallery like the cresting of a crown. Sometimes the upper storey of the tower is made octagonal, and is set back so as to allow of a passage round with parapet or battlement, as at St Mary's, Bloxham, St Peter and St Paul, Seton, and St Mary, Castlegate, York. The most important groupings are those which surmount the towers of the English cathedrals; at Lichfield square turrets of large size with richly crocketed pinnacles; at Peterborough, a peculiar but not happy arrangement where a lofty spire covers over the buttress between angle turret and spire; and at

Salisbury an octagonal pinnacle at the angle and a triangular spire light against the spire. The happiest combination of all, however, is perhaps the spire of St Mary's, Oxford, with three ranges of angle niche-groups set one behind the other, forming with the centre spire a magnificent cluster of spires; the niche gables and pinnacles are all enriched with crockets and the ball flower in the arch mouldings.

Reference has already been made to two of the French spires, at Chartres and St Denis; there is nothing like the diversity of design in France, however, when compared with those in England, and there are but few on the crossing of nave and transept; the towers were built to receive them, as at Amiens, Reims and Beauvais, but for some reason not carried above the roof, possibly from some doubt as to the expediency of raising stone lanterns and spires of great weight on the four piers of the crossing; on the other hand their places were taken by constructions in timber covered with lead, of immense height and fine design. There was a 13th-century flêche on the crossing of Notre-Dame, Paris, taken down soon after the beginning of the 19th century, of which the existing example by Viollet-le-Duc is a copy. The same fate befell that over the Sainte Chapelle, Paris, being reconstructed about 1850 by Lassus. The flêche at Amiens, though of late date (*c.* 1500), is still in good preservation and is a remarkable work; above the ridges of the roofs of nave and transept, and octagonal in plan, are two stages, the upper one set back to allow of a passage round, and, above the cresting of the latter, a lofty octagonal spire with spire lights at the base on each side, crockets up the angles, and other decorations in the lead work with which it is covered. Including the vane, from the ridge of roof the height is 182 ft. Of timber flêches covered with slates there are many examples in the north of France, those at Orbais (Marne) and the abbey at Eu (Seine Inférieure) being the best known. Returning to stone spires, those on the west front of St Stephen's, Caen (Abbaye-aux-Hommes), are good examples with lofty octagonal turrets and pinnacles at west angle and spire light between, and among others are those of St Pierre at Caen, Senlis, Coutances, Bayeux, and many others in Calvados, and at Soissons, Noyon and Laon in Picardy. One of the most beautiful spires in France, though of late date, is that of the north-west tower to Chartres Cathedral. In the south of France, in the Charente and Périgord, the stone spire takes quite another form, being of much less height, of convex form, and studded with small scales, giving somewhat the appearance of a pine cone, with small pinnacles also with scales, and carried on a group of shafts at the angles of the tower. The west tower of Angoulême Cathedral, the central towers of Saintes Le Palud, and Plassac in the Charente, and the tower of St Front, Périgueux, and Brantôme in Périgord, have all spires of this kind, of which a small example crowns the Lanterne des Morts at Cellefrouin. The German towers are generally covered with roofs only, of varied form, but at Ulm, Strassburg, Freiburg and Cologne is a remarkable series of traceried spires in stone, of great elaboration and showing great masonic ability, but wanting in repose and solidarity, and the same applies to the spire at Antwerp. In Spain there are not many examples of note, the spire at Burgos suggesting in its outline and want of height the influence of the Périgordian spires, and that at Salamanca the influence of those in the north of France.

Looking upon the spire as the crowning feature of a tower, those of the Renaissance period must be included here, though as a compromise they are often termed "steeples." Of these the finest and most varied are those by Wren in London, among which that of Bow Church and St Bride's, Fleet Street, are the best known, the former with two stages of lanterns with detached columns round, and the latter octagonal on plan with five stages, set one behind the other, with arches in centre of each face and pilasters at the angles. St Antholin, now destroyed, was the only example based on a Gothic prototype; it consisted of an octagonal spire with Renaissance spire lights and angle finials resting on the upper octagonal storeys of the tower. St Margaret Pattens somewhat resembles it, but the tower has a balustrade round and the angle pinnacles are in the form of obelisks, a favourite Renaissance interpretation of the Gothic finial, which is found in other churches, as in those of St Martins-in-the-Fields by Gibbs and St Giles-in-the-Fields by Flitcroft. Hawksmoor apparently based his spire of St George's, Bloomsbury, which consists of a series of lofty steps, and is crowned with a statue of George I., on that of the mausoleum at Halicarnassus. In France, Italy and Spain, lanterns usually terminate the towers. The spire of the Seo at Saragossa in design somewhat resembles those of Wren, being one of the few examples worth noting. (R. P. S.)

SPIRE LIGHT (Fr. *lucarne*), the term given to the windows in a spire which are found in all periods of English Gothic architecture, and in French spires form a very important feature in the composition. There is an early example in the spire of the cathedral at Oxford; they are not glazed, and have occasionally, if of large size, transoms to strengthen the mullions.

SPIRES (Ger. *Speyer* or *Speier*), a town and episcopal see of Germany, capital of the Bavarian palatinate, situated on the left bank of the Rhine, at the mouth of the Speyerbach, 16 m. S. of Mannheim by rail. Pop. (1905), 21,823. The principal streets are broad but irregular, and the general appearance of the town little corresponds to its high antiquity, owing to the fact that it was burned by the French in 1689. The only important ancient building that survived the flames is the cathedral, a very large and imposing basilica of red sandstone, and one of the noblest examples of Romanesque architecture now extant. Beyond the general interest attaching to it as one of the old Romanesque churches of the Rhineland, Spires Cathedral has a peculiar importance in the history of architecture as probably the earliest Romanesque basilica in which the nave as well as the side arcades was vaulted from the first (see ARCHITECTURE: *Romanesque in Germany*). Built in 1030–1061 by Conrad II. and his successor, this church has had a chequered history, its disasters culminating in 1689, when the soldiers of Louis XIV. burned it to the bare walls, and scattered the ashes of the eight German emperors who had been interred in the king's choir. Restored in 1772–1784 and provided with a vestibule and façade, it was again desecrated by the French in 1794; but in 1846–1853 it was once more thoroughly restored and adorned in the interior with gorgeous frescoes at the expense of the king of Bavaria. The large cathedral bowl (Domnapf) in front of the west façade formerly marked the boundary between the episcopal and municipal territories. Each new bishop on his election had to fill the bowl with wine, while the burghers emptied it to his health. The heathen tower to the east of the church, on foundations supposed to be Roman, was probably part of the town-wall built in 1080 by Bishop Rudger. Of the Retscher, or imperial palace, so called because built after the model of the Hradschin at Prague, only a mouldering fragment of wall remains. It was in this palace that the famous Diet of Spires met in 1529, at which the Reformers first received the name of Protestants. The Altpörtel (*alta porta*), a fine old gateway of 1246, is a relic of the free imperial city. Among the modern buildings are several churches and schools, a museum and picture gallery, &c. Spires, although rebuilt in 1697, has never recovered from the injuries inflicted by the French in 1689. Its trade is insignificant, although it still has a free harbour on the Rhine. Its manufactures include cloth, paper, tobacco and cigars, sugar, sugar of lead, vinegar, beer and leather. Vines and tobacco are grown in the neighbourhood.

Spires, known to the Romans as *Augusta Nemetum* or *Nemetae*, and to the Gauls as *Noviomagus*, is one of the oldest towns on the Rhine. The modern name appears first under the form of Spira, about the 7th century. Captured by Julius Caesar in 47 B.C., it was repeatedly destroyed by the barbarian hordes in the first few centuries of the Christian era. The town had become an episcopal seat in the 4th century; but heathenism supervened, and the present bishopric dates from 610. In 830 Spira became part of the Frankish Empire, the emperors having a "palatium" here; and it was especially favoured by the Salic imperial house. The contentions between the bishops and the citizens were as obstinate and severe as in any other city of Germany. The situation of the town opposite the mouths of several roads through the Rhine valley early fostered its trade; in 1294 it rose to be a free imperial city, although it owned no territory beyond its walls and had a population of less than 30,000. It enjoyed great renown as the seat of the imperial supreme court from 1527 till 1689; it was fifth among the free cities of the Rhine, and had a vote in the Upper Rhenish Diet. Numerous imperial diets assembled here. From 1801 till 1814 it was the capital of a department of France; but it was restored to Bavaria in the latter year. By the Peace of Spires in 1544 the Habsburgs renounced their claims to the crown of Sardinia.

SPIRITS.[1] The original meaning of the word spirit (Lat. *spiritus*, from *spirare*) was wind in motion, breath, the soul, and hence it came to denote that which gives life or vigour to the human body and other objects, and it is, therefore, synonymous with everything eminently pure, ethereal, refined or distilled. In popular chemical nomenclature the term "spirit" in its former sense is still occasionally encountered, for instance, "spirits of salts" for hydrochloric acid. The spirits of the British Pharmacopoeia (*e.g. sp. aetheris nitrosi*; *sp. chloroformi*; *sp. camphorae*) are solutions of various substances obtained either by distilling these with, or dissolving them in, the rectified spirit of the Pharmacopoeia, which latter is pure alcohol with 16% by weight of water.

In the modern sense, spirits may be broadly defined as the products resulting from the distillation of saccharine liquids which have undergone alcoholic fermentation. Spirits of wine means rectified spirit of a strength of 43 degrees over proof and upwards. By rectified spirit is meant spirit rectified at a licensed rectifier's premises. Proof spirit, which is the standard spirit of the United Kingdom, is legally defined (58 Geo. III. c. 28) as a spirit which at 51° F. weighs exactly twelve-thirteenths of the weight of an equal volume of distilled water. The strength of proof spirit at 60° F.—the temperature now generally employed for official calculations—is now officially regarded as being equal to a spirit containing 57·06% by volume, or 49·24% by weight, of absolute alcohol. Spirit which possesses a greater or smaller alcoholic strength than proof is described as being so many degrees over or under proof, as the case may be. The strength is legally estimated by Sykes's hydrometer, which was legalized in 1816 by 56 Geo. III. c. 40. The degrees "over" or "under" proof as ascertained by Sykes's hydrometer are arbitrary percentages by volume of a standard spirit contained in the spirit under examination. This standard spirit is proof spirit. For example, by a spirit of strength 75·25 degrees over proof (absolute alcohol) is meant a spirit of such a strength that 100 volumes of the same contain an amount of spirit equal to 175·25 volumes of the standard (proof) spirit. A spirit of 25 degrees under proof is one of which 100 volumes contain only as much alcohol as do 75 (*i.e.* 100−25) volumes of proof spirit. According to Nettleton, "proof spirit" would appear to be the outcome of an attempt to produce a mixture of pure alcohol and water, containing equal weights of the constituents. The term "proof" probably originated from a rough test for spirituous strength formerly employed, which consisted in moistening gunpowder with the spirit and applying a light. If the gunpowder did not ignite, but the spirit merely burned away, the spirit was regarded as being under proof, *i.e.* it contained so much water that the gunpowder became moist and refused to deflagrate. The basis of the standard of other countries is almost invariably the unit volume of absolute alcohol, the hydrometers, or rather "alcoholometers"—such as those of Gay-Lussac and of J. G. Trálles—employed indicating the exact quantity of alcohol in a mixture at a standard temperature, in percentages by volume. In the United States the term "proof" is also employed, American proof spirit being a spirit which contains 50% of alcohol by volume at 60° F. American "proof" spirit is, therefore, considerably weaker than British "proof." Allowing for this difference and also for the fact that the American standard gallon (which is really the old English wine-gallon) is equal to 0·833 of an imperial gallon, the American "proof" gallon roughly equals 0·73 of a British proof gallon.

[1] For the sense of disembodied persons, see SPIRITUALISM.

Historical.—The art of distillation, more particularly the preparation of distilled alcoholic fluids for beverage and medicinal purposes, is of very ancient origin. It is probable that the art of making spirits was well known many centuries before the advent of the Christian era. According to T. Fairley, the Chinese distilled liquor "sautchoo" was known long before the Christian era, and "arrack" was made in India at a date as remote as 800 B.C. Aristotle in his *Meteorology* (lib. ii. ch. ii.) says "Sea-water can be rendered potable by distillation: wine and other liquids can be submitted to the same process. After they have been converted into humid vapours they return to liquids." There is, on the whole, little doubt that spirits were manufactured in Egypt, India, China, and the Far East generally, as far back as 2000 B.C. Figs. 1–4 (from Morewood's *Inebriating Liquors*, published in 1838) show very ancient forms of stills in use in China, India, Tibet and Tahiti.

FIG. 1.—Ancient form of Still, used in China.

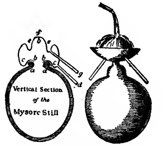

FIG. 2.—Ancient form of Still, used in Central India.

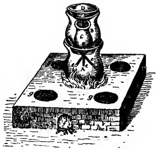

FIG. 3.—Ancient form of Still, used in Tibet.

As far as can be ascertained the oldest reference to the preparation of a distilled spirituous liquor in the British Isles is contained in the "Mead Song" written by the Welsh bard, Taliesin, in the 6th century. He said "Mead distilled I praise, its eulogy is everywhere," &c. (Fairley, *The Analyst*, 1905, p. 300). The same authority points out that the knowledge of distillation in the British Isles was independent of the art of distillation from wine, seeing that distillation from grain was known in Ireland before the art of making wine came to Europe. An Irish legend states that St Patrick first taught the Irish the art of distillation; but, however that may be, it is certain that at the time of the first English invasion of Ireland (1170–72) the manufacture of a spirit distilled from grain (*i.e.* whisky) was known to the inhabitants of that country. It is probable that grain spirit was first prepared in the Far East, inasmuch as a spirit distilled from rice and other grains was made in India before the Christian era. The establishment of regular distilleries in England appears to date back to the reign of Henry VIII., and they are said to have been founded by Irish settlers who came over at that time. It is difficult to obtain exact data

FIG. 4.—Ancient form of Still, used in Tahiti.

regarding the origin of the distilling industry in Scotland, but, as Fairley says, it is probable that distilling was carried on there almost as early as in Ireland. At the time of the Tudors Scotch whisky was held in great repute in England. The production of a spirit from wine (*i.e.* brandy) appears to have been known in the 9th century; but, according to Morewood, the first attempt at the distillation of wine in France is attributed to Arnaldus de Villa Nova, in the 13th century. As a manufacturing industry the distillation of brandy in France began in the 14th century. The history of the spirit industry in the United Kingdom is, as Nettleton has well pointed out, inseparably connected with questions of taxation. According to one writer, it was not until 1660 that an excise duty was first imposed on the consumption of spirit (" aqua vitae ") in the United Kingdom, but it appears probable that the industry generally was taxed in one form or another in the reign of Elizabeth, when it first began to assume considerable importance. No record, however, of the quantity of spirit on which duty was charged was kept until 1684. In that year duty was paid on 527,492 gallons. At the end of the century the consumption reached 1,000,000 gallons, and in 1745 it had risen to a quantity equivalent to about 5,000,000 gallons at proof. Cromwell imposed a tax of 8d. per gallon, but this was soon lowered to 2d. In 1751 a tax equivalent to 1s. per proof gallon was imposed, and in 1766 this was further increased to 2s. After this various changes and complex methods of assessing the duty were introduced (see Nettleton, *The Manufacture of Spirit*, Marcus Ward, 1893) until, in more modern times, a more rational and uniform system was introduced.

Conditions of Manufacture.—The principal act now governing and regulating the manufacture of spirits and the working of distilleries in Great Britain is the Spirits Act of 1880. The provisions of this and of the other acts bearing on the subject are exceedingly numerous and complicated, and, therefore, only a few of the chief points can be set forth here, so that an adequate appreciation may be gained of the arduous and rigid conditions under which the spirit manufacturer is, in order to ensure the safeguarding of the revenue, constrained to carry out his operations. A distillery must not, without permission, be carried on at a greater distance than half a mile from a market town, nor may it be situated within a quarter of a mile from a rectifying establishment. A distiller must give notice of the erection of new plant or apparatus, of the time of brewing, of the removing of sugar from store or of yeast from wort or wash, of the making of " bub," of the locking of the spirit receiver supply pipe, &c. He may use any material he pleases, provided that the gravity of the wort can be ascertained by the saccharometer, but he may not brew beer nor make cider, wine nor sweet wines. When the worts are collected in the wash-back (fermenting vessel) a declaration must be made at once, specifying the original gravity and the number of dry inches remaining in the back. At the end of every distilling period a return must be delivered showing (*a*) the quantity of brewing materials used, (*b*) the quantity of wort or wash attenuated and distilled, (*c*) the quantity of spirits produced at proof-strength, and (*d*) the quantity of " feints " remaining. Regulations also exist with regard to the amount of " bub " (see below) that may be added to the worts, or the quantity of yeast that may be removed from the wash, concerning the time permissible for drawing over spirit at the various stages, as to placing in and taking spirit out of store, the number and size of vessels, the locking of the latter, and the painting of the pipes carrying various liquids in certain colours. The methods of assessing the duty are threefold, and whichever of these methods gives the highest return is the one adopted. The first is the " attenuation charge." This consists of levying the charge due on one gallon of proof spirit for every hundred gallons of worts collected and for every five degrees of attenuation observed, the latter being calculated by taking the difference between the highest specific gravity of the worts and the lowest gravity of the wash after complete fermentation. Secondly, there is the " low-wines charge," calculated upon the bulk-quantity at proof-strength of the low wines produced by the distillation of the wash; and lastly, the " feints and spirits charge." This is the method usually adopted, as it generally gives the highest results; it is assessed on the number of bulk gallons at proof of the feints and spirits produced by the final distilling operations. The duty, which was fixed at 10s. per proof gallon in 1860, remained at that rate until 1890, when an addition of 6d. was made, but a further increase to the like amount made in 1894 was remitted in the next year owing to the unsatisfactory results obtained. The rate remained at 10s. 6d. until 1900 when it was raised to 11s., a further increase being made in 1909–1910.

Legally, the word " spirit " implies spirit of any description, and all liquors, mixtures and compounds made with the same. In the same way plain spirit is any British spirit which has not been artificially flavoured, and to which no ingredient has been added subsequent to distillation.

The extremely severe and inelastic provisions of the acts governing the manufacture of spirit in the United Kingdom have proved to be a very serious impediment to the development of the spirit industry on modern lines, and have placed the British manufacturer at a considerable disadvantage as compared with his foreign competitors. There is little doubt that the enormous revenue derived from the spirit industry could be adequately safeguarded in a manner more consistent with the development of the industry on sound commercial and technological lines than it is at present.

Production and Consumption.—The production of spirit in the United Kingdom amounted in 1907 to roughly 50,000,000 proof gallons, the consumption to a gallon per head of population. In the decade 1880–1890 the quantity of spirits distilled remained practically stationary at about 40,000,000 gallons, but during the ten years 1890–1900 there was a rapid increase, the maximum being attained in 1898, when nearly 64,000,000 gallons were produced. A point had then been reached at which the production had considerably outstripped the consumption, due in part to the desire of the spirit trade to meet the increased demand for " matured " spirits, and in part to the fact that an excessive amount of capital had, owing to the increased popularity of Scotch whisky, been attracted to the distilling industry. This over-production led to a vast increase in the quantity of spirit remaining in warehouse. In 1906 production and consumption were about equal, and the quantity of spirit in warehouse represented roughly a five years' supply.

The following figures regarding production, consumption, duty, &c., need no explanation:—

United Kingdom

1905–1906	49,214,165	32,486,958	0·75	7,049,798	5,663,429	163,519,957	17,765,352
1906–1907	50,317,908	32,511,316	0·74	7,341,077	6,055,285	161,648,409	17,745,125

The importation of foreign potable spirits into the United Kingdom has fallen off materially since 1870–1875, during which period it stood at 16,000,000 to 17,000,000 gallons. This is chiefly due to the decreased consumption of brandy, and, to a smaller extent, to the diminishing importance of rum and other foreign spirits. The most remarkable change in this connexion is in the case of foreign methylated spirit. At one time (1891) the quantity of this article imported

2. *Statistics regarding Imported Spirits.*

Year.	Total imports (proof gallon).	Consumption per head of population (proof gallon).	Nature of spirits (proof gallon).	Retained for methylation.
1895–1896	10,821,518	0·20	Rum . . 6,217,469 Brandy. . 2,668,616 Other sorts. 1,935,433	91,990
1902–1903	13,130,182	0·20	Rum . . 6,719,452 Brandy. . 3,081,525 Other sorts. 2,617,090	1,212,001
1905–1906	8,228,435	0·16	Rum . . 4,879,958 Brandy. . 2,456,773 Other sorts. 891,704	nil.
1906–1907	8,129,503	0·17	Rum. . . 5,110,345 Brandy. . 1,942,415 Other sorts. 1,076,743	nil.

was almost equal to the amount manufactured in the United Kingdom, the figures being 1,995,782 gallons for the home produce and 1,456,108 for the foreign. For various reasons—chiefly owing to the surtax of 4d. per gallon on all foreign spirit—the quantity imported has gradually dwindled away, and at the present time is practically negligible. The principal spirit-producing countries are Russia and Germany, the United States coming next, and then France, Austria and the United Kingdom in succession, followed by Hungary, Holland and Belgium. The following are the figures for 1905:—

	Proof gallons.	
Russian Empire	161,366,000	(1904)
Germany	146,014,000	
United States	125,042,000	
France	160,584,000	
Austria	55,682,000	
United Kingdom	48,520,000	
Hungary	40,216,000	
Holland	13,552,000	
Belgium	11,924,000	

If we except Canada and the Cape (which make roughly 6,000,000 and 1,500,000 gallons respectively), the production of the British Empire, apart from the United Kingdom, is very small. British Guiana exports 3,000,000 to 4,000,000 and Jamaica about 1,500,000 gallons of rum.

With regard to the consumption in gallons per head, Denmark stands first with 2·4, then follows the Austro-Hungarian Empire, with 1·98, Germany with 1·43, Holland with the same figure, France with 1·37, Sweden with 1·36, the United States with 1·26, Belgium with 1·10, and last the United Kingdom with 0·91. The consumption in Russia is about equal to that of the United Kingdom. The figures given are for the year 1905. In the British colonies Western Australia comes first with a consumption per head of 1·33 gallons; and then in order Queensland 1·32 gallons; Canada 0·94 gallon; New South Wales 0·77 gallon; New Zealand 0·73 gallon; Victoria 0·64 gallon; the Cape 0·68 gallon, and South Australia 0·47 gallon. Of the spirits distilled in the United Kingdom, Scotland produces roughly one half, England and Ireland about one quarter each. Although the number of distilleries in England and Ireland has varied but little of recent years, the number in Scotland increased from 120 in 1880 to 161 in 1899. In 1906 the actual numbers were—Scotland 150; Ireland 28; England 8. The apparent anomaly between the number of distilleries and the quantity of spirit produced in different parts of the kingdom is explained by the fact that the great majority of the distilleries in Scotland and Ireland are small, pot-still distilleries, whereas the English works are all of considerable capacity. It is difficult to arrive at any satisfactory figure with regard to the amount of capital invested in British and Irish distilleries, but it probably exceeds twenty millions.

Illicit distillation has almost ceased to exist in Great Britain, but in Ireland the number of annual seizures under this heading is still considerable. In 1906–1907, out of a total of 974 detections and seizures, 968 were in Ireland.

The spirit produced in the United Kingdom is made almost exclusively from malt, unmalted grain (chiefly maize, rye, barley, wheat and oats) and molasses. The relative proportion of malt to unmalted grain has shown a slight tendency to increase during the past twenty years, but the quantity of molasses employed has increased very largely in the same period, owing mainly to the fact that home-made spirit has largely displaced the foreign article for several industrial purposes and particularly for methylation. The estimated quantities of the various materials employed in 1883 and 1906 respectively were as under:—

Year.	Malt (quarters).	Unmalted grain (quarters).	Molasses and sugar (cwt.).
1883	859,363	1,054,081	165,529
1906	1,151,199	1,090,286	985,808

With regard to the materials employed in the manufacture of spirits in France, roughly 80–90% now consist of maize (and other starchy substances), beetroot and molasses, whereas in 1840 nine-tenths of the alcohol produced was derived from the grape and other fruits. This change is due in part to the ravages of the oïdium disease (1850–1857) and the phylloxera (1876–1890), which destroyed an immense number of vines, but chiefly to the increased demand for commercial spirit in the arts and manufactures, and also to the improved methods for obtaining a high-class spirit from practically any starchy or saccharine material. In 1905 the number of alcohol units (the unit = 1000 hectorlitres of pure alcohol) distilled from maize and other starchy materials was 589, from molasses 516, from beetroot 1002, from wine, cider, lees and fruits 499. In Germany roughly 75% of the spirit manufactured is derived from potatoes. In 1905 the total spirit distilled amounted to 3786 units (of 1000 hectolitres of pure alcohol), of which 2877 units were obtained from potatoes, 765 units from grain and 144 units from molasses and other material. In Russia spirits are distilled chiefly from potatoes and rye, in the United States from maize.

Manufacture.—The manufacture of spirits consists broadly in converting starchy or saccharine matter into alcohol, the latter product being subsequently separated, concentrated and rectified. When spirits are made from a purely saccharine material the process of conversion into alcohol is a relatively simple one, but where farinaceous raw products are employed it is primarily necessary to transform the starch contained in them into sugar. The main varieties of spirits manufactured from sugar, or from sugar-containing materials, are:—

Sugar-derived Spirits

Raw Material.	*Product.*
Wine.	Brandy.
Sugar-cane and cane molasses.	Rum.
Beetroot; beet molasses.	Industrial alcohol.

Occasionally wine, cider, perry and cane molasses are also employed for making either plain potable spirit or industrial alcohol, and at times cane molasses (chiefly obtained from Cuba and the West Indies) are used somewhat extensively in England for the manufacture of plain spirit. Occasionally, also, plain potable spirit is derived from beets, but rarely from beet molasses, the spirit derived from the latter being somewhat difficult of rectification.

The chief spirits derived from starchy materials, and their corresponding raw materials, are as follows:—

Starch-derived Spirits

Raw Material.	*Product.*
Cereal grains: chiefly barley, rye, oats, wheat and maize	Whisky, "corn brandy," "vodka," plain spirit; industrial alcohol.
Potatoes	Industrial alcohol.

A. *Spirits Derived from Saccharine Materials.*—The manufacture of the finer brandies, such as those of Cognac, is, as far as the processes involved are concerned, by no means a complex matter. The excellence of this class of spirit is due mainly to the character of the wine employed and to the great experience of the distillers in selecting and blending the raw materials and finished products. The character of the wine is, of course, chiefly due to the peculiar soil and climatic conditions, and in some degree to the methods of cultivation. The latter, it may be added, have since the reconstitution of the Charente vineyards subsequent to their partial destruction by the phylloxera (see Brandy) been much improved. In the pre-phylloxera days the vineyards were planted and cultivated in a very rough and ready fashion, without any attempt at regularity of planting. The result was that the vines spread practically unrestrained in every and any direction. In consequence there was a great irregularity of growth, feeble and hardy plants being found side by side, and the yield was poor. In vineyards constructed in the modern style the vines are planted in regular rows, and the bushes are, with a view to obtaining regular and rapid

Brandy.

ripening, methodically supported by wire. The wines produced by the Charente vineyards are of a light (white) character and possess no marked "bouquet," but they nevertheless produce a spirit of a peculiarly fine and delicate character. It is remarkable that the fuller and more aromatic wines of the Gironde and of Burgundy, for instance, are not so suitable for the manufacture of brandy as the relatively poor growths of the Charente. The apparatus employed for the distillation of the fine Cognac brandies is generally of a very simple pot-still type. Fig. 5 depicts the still-room of a Charente distillery

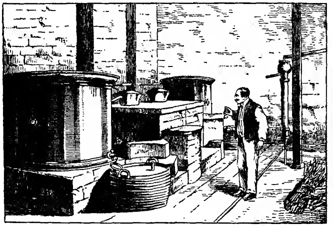

FIG. 5.—Old Cognac Pot-still.

of former times, and fig. 6 shows one of Messrs Martell's distilleries in Cognac, equipped on modern lines. It will be seen that, in principle, there is very little difference between

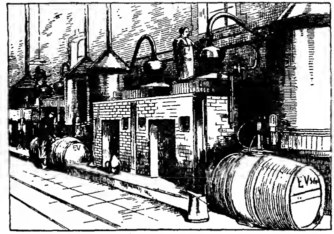

FIG. 6.—Modern Cognac Pot-still. (Martell & Co.)

the two sets of plant, the reason being that experience has shown that for wines producing the finest brandies, the simplest form of still is also the best. For the distillation of wines not of the highest quality (from the brandy distillers' point of view) more complicated apparatus is employed, as the spirit from these wines must be more highly rectified than is the case with the finest brandies. Broadly speaking, it may be said that the type of still is suited to the production in the most economical manner of the best spirit to be obtained from the wine of a particular district. In Cognac, brandy is generally, but not universally, made by the "brouillis et repasse" system, this being a double distillation in a simple pot-still. The stills are (compared with whisky pot-stills) very small, holding roughly one hundred gallons, and the distillation is conducted very slowly and carefully, lasting about eight hours. Sometimes the whole of the spirit is collected in one receiver (corresponding to the low wines of Scotch whisky), but frequently the "brouillis," as the results of the first distillation are termed, are divided into several fractions. The "brouillis" which contain about 25 to 35% of alcohol are redistilled, this second distillation being called the "bonne chauffe" or "repasse." The first runnings—which vary in quality according to the quality of the wine, the manner of heating, &c.—are termed "produit de tête" or "têtes," and are separately collected and mixed with the "brouillis" of the following operation. The spirit which next comes over (starting at a strength of about 80% and running down to about 55%) is the "cœur," and as a whole, marks roughly 66 to 70% of absolute alcohol by volume. The residue in the still is then run down to water, and the spirit so obtained, which shows 20 to 25%, is called "seconde," and is either mixed with a fresh charge of wine or rectified separately, the stronger portion being mixed with the "brouillis," the weaker with a charge of wine (see BRANDY).

Rum.

There are two main kinds of rum, namely, Jamaica rum and rum of the type prepared principally in Demerara and Trinidad (see RUM). There are two varieties of Jamaica rum (*a*) the common clear rum, and (*b*) flavoured, or "German" rum. (*a*) "Common clear" rum is prepared from a mixture of sugar-cane molasses, "skimmings" (the scum from the boiling cane juice) and "dunder," this last name being given to the spent lees from previous distillations. Previous to use the "skimmings" are subjected to acid fermentation either alone or in conjunction with "trash" (crushed cane). The wort, which on the average contains about 10 to 15% of sugar, ferments very slowly, owing to the fact that very little yeast—the latter being derived from the cane rind—is present. Roughly five to ten days are occupied by this operation. At first the fermentation is mainly alcoholic, but it rapidly assumes an acid character, owing to the presence of a great number of acidifying bacteria derived from the "dunder" and "skimmings." The distillation of the fermented wort is carried out in pot stills heated by fire or steam, either of a simple type or provided with rectifiers. In the former case two distillations are necessary, the first resulting in the production of a weak alcoholic liquid termed "low wines," the second, which consists in a rectification of the low wines, producing "high wines" or strong rum. The other type of still is provided with two rectifiers, which are interposed between the still and the condensing worm. These are charged with low and high wines respectively. The first runnings of the still (25 to 40 o.p.) constitute the rum proper, the next fraction the high wines, and the final distillate the low wines. (*b*) Flavoured or "German" rum is prepared from the same materials as the "common clear" variety, with the addition of "acid" and "flavour." "Acid" is obtained by acidifying fermented cane juice by means of cane "trash" and refuse from the wash backs. "Flavour" is prepared in much the same way as "acid," except that "dunder" sediment is also added. The fermentation, which is to a very great extent bacterial, results in the formation of large quantities of acid, including much butyric acid and compound esters. The distillation of "flavoured" rum is carried out in much the same manner as that of the "common clear." The manufacture of "Demerara rum" is differentiated from that of the Jamaica varieties mainly by the fact that the fermentation in the former case is practically purely saccharomycetic (*i.e.* yeast), whereas the latter is largely schizomycetic (*i.e.* bacterial). For the distillation of the Demerara rums, which are much lighter in flavour than the Jamaica varieties, stills of the "patent" (see below) or rectifying type are frequently employed (see RUM and ARRACK).

For the manufacture of industrial spirit from saccharine materials see below, under *Industrial Alcohol.*

B. *Spirits Derived from Starchy Materials.*—The manufacture of spirit from saccharine materials is, as we have seen, a relatively simple operation, the sugar being transformed into alcohol by fermentation, and the latter then distilled off. To convert starchy matter into alcohol is a much more complicated matter. To the operations necessary for the transformation of sugar into spirit, must, in the case of starchy materials, be added that of converting the starch into sugar. This is accomplished either by the action of a diastatic ferment, such as that present in malted grain (see BREWING) or secreted by certain living organisms, or by an acid such as sulphuric acid. The latter process is little employed at the present time. The materials employed by the distiller, and the methods of preparation and treatment to which they are subjected before and after entering the distillery, are in some respects similar, in others materially different, from those employed by the brewer. The materials most frequently employed are maize, rye, barley malt, raw barley, oats, wheat and potatoes. Comparing the main operations (apart from the actual process of distillation) of the brewer with those of the distiller, it is true that these are identical in the sense that they consist in the conversion of starch into sugar and of the latter into alcohol; but whereas the object of the brewer is to produce beer, of which alcohol forms only a relatively small proportion, the distiller, broadly speaking, desires to produce alcohol, and it is this fact which is responsible for the differences alluded to above.

Distillery Malting.—Where malt is employed as the main raw material, as, for instance, in the case of Scotch pot-still whiskies, and also, but to a minor degree, in Irish pot-still whiskies and patent-still whiskies, the process of preparation does not, except in some specific particulars, differ very widely from that used in making brewer's malt (see MALT). With regard to the barley employed for this purpose, certain qualities which are of the greatest importance to the brewer, such as the nature of the husk, colour, and friability of the starch, are of little interest to the distiller, and providing that the grain is sound and that it contains a high percentage of starch and malts as well, it will pass muster as an average distillery material. It is usual to give barley intended for patent-still work a rather longer period in the steep and on the floors than in brewery malting, and it is well to treat the steep-water with some antiseptic, preferably lime, as the distiller has not the opportunity of lessening the dangers of bacterial infection at subsequent stages which is afforded to the brewer by the boiling and hopping of the wort. In distilleries where barley malt is not used as the main raw material, but mainly or chiefly as a diastatic agent (for instance, in potato and maize distilleries on the continent of Europe), the so-called "long" malt process is widely employed. This consists essentially in subjecting the grain first to a somewhat lengthy steep (until the increase in weight due to the absorbed water is about 40 to 45%), and secondly to a very prolonged "flooring" at a moderate temperature, great attention being paid to the conditions of ventilation and humidity. It was formerly believed that the germinating barley grain attains its maximum of diastatic power after a very short period, and that when the acrospire is three-quarters "up" and the rootlets say one and a half times the length of the grain, the malt is ready for removal from the floor. M. Delbruck, Hayduck and others have, however, shown that this is not the case, and the practical results obtained by adopting the twenty days' "flooring" period (and its attendant conditions) have amply confirmed the scientific researches on this subject.

Hayduck has shown that the relative diastatic strengths of "short" (seven to ten days) and "long" (twenty days) malt are, (1) for heavy barleys as 100: 128·5 (average), (2) for light barleys as 100: 160·5 (average). In contradistinction to the brewer (who can only use it on exceptional occasions and for special purposes), the distiller prefers, whenever this is feasible, to use green malt rather than kilned malt. One of the principal objects of kilning brewing malt is to restrict the diastatic power; but this is the very factor which the distiller desires to preserve, as the green malt possesses roughly twice the diastatic activity of high kilned malt. It is obvious that the distiller, who regards his malt merely as a starch-converting agent, will, *ceteris paribus*, use as little kilned malt as possible. The malt whisky distiller cannot, however, use green malt, as he relies to a great extent on the kilning process for the development of the peculiar flavour characteristic of the article he produces. Moreover, it is frequently difficult during hot weather to obtain a satisfactory green malt supply, especially as the latter will not bear carriage for any distance, and distillers who make pressed yeast (commonly called "German" yeast) find that a proportion of kilned malt is necessary for the satisfactory manufacture of this article. When the distiller is unable to use green malt he will, by preference, use a malt which has been kilned at as low a temperature as possible. Under these conditions the kilning is little more than a drying operation, and the temperature is rarely raised above 130° F.

Although green or low-dried barley malt is the saccharifying agent usually employed both in the United Kingdom and on the continent of Europe, malts prepared from other cereals are not infrequently employed for this purpose. According to Glaser and Moransky the relative starch-transforming capacities of the various malted grains, taking barley as the unit, are as follows:—

Barley malt	1·00
Rye malt	0·93
Wheat malt	1·08
Oat malt	0·30
Maize malt	0·28

Oat malt, notwithstanding its low transforming power, possesses certain advantages, inasmuch as it is easily and rapidly prepared, it acts very quickly in the mash tun, and its diastatic power is well maintained during fermentation. Rye is best malted in conjunction with a little barley or oats, as it otherwise tends to superheat and to grow together in a tangled mass.

Distillery Mashing.—Distillery mashing, although outwardly very similar to the process employed in brewing, differs very widely in some important particulars. In brewing all the necessary fermentable matter is formed from the starch by the mashing operation. The wort so obtained is then hopped and sterilized. This method of working, however, cannot be adopted by the distiller. The brewer must have a certain proportion of dextrinous, non-fermentable carbohydrate matter in his wort; the distiller, on the contrary, desires to convert the starch as completely as possible into fermentable, that is, alcohol-yielding, material. This result is obtained in two ways: first, by mashing at low temperatures, thus restricting the action of the diastase less than is the case in the brewer's mash; and, secondly, by permitting the diastatic action to continue during the fermentation period. Low temperature mashing alone will not have the desired effect, for part of the dextrinous bodies resulting from diastatic starch-transformation are not further degraded by diastase alone, but are rendered completely fermentable by the combined action of diastase and yeast. Hence the distiller is unable to boil, that is, to sterilize his wort, as he would thereby destroy the diastase entirely. In this he is at a serious disadvantage compared with the brewer, as an unsterilized wort is very liable to bacterial infection. The latter danger prevents the distiller from taking full advantage of the benefits of low-temperature mashing, and he is obliged to heat his mash to a temperature which will, at any rate, be a partial safeguard against the bacterial evil. The method employed varies according to the nature of the mash and the quality of the spirit that it is desired to obtain, but in principle it consists, or should consist, in bringing the mash as rapidly as possible to the temperature of maximum saccharification, keeping the whole at this point for some little time, then heating to the temperature of maximum liquefaction, and subsequently to as high a temperature as is consistent with the thickness of the mash and the preservation of sufficient diastase for the fermenting period.

The Fermenting Operations.—The conditions and methods of distillery fermentation vary considerably, and in some respects radically, from those employed in the brewery. In order to obtain the maximum alcohol yield the distiller is obliged to work with unsterilized wort, and at relatively high temperatures. The necessity for the former condition has already been explained, but the latter is due to the fact that the optimum working capacity of distillery yeast is reached at a temperature markedly above that most favourable to brewing types. Apart from this, if the distiller worked at brewing temperatures the brewing yeasts would predominate, and these produce less alcohol than the distillery types. Thus at 75° F. (and above) distillery yeasts tend to predominate. The conditions of fermentation which are more or less forced upon the distiller are unfortunately also very favourable to the development of bacteria, and if special methods are not adopted to check their development, the result would seriously affect not only the quantity but also the quality of alcohol produced. The micro-organisms chiefly to be feared are those belonging to the class of fission fungi (schizomycetes), such as the butyric, the lactic, the mannitic, and mucic ferments.

Souring.—It has long been known to practical distillers that in order to avoid irregular (bacterial) fermentations it is necessary either to let the wort "sour" naturally, or to add a small quantity of acid (formerly sulphuric acid was frequently employed) to it before pitching with yeast. The reason for this necessity was until recent times by no means clear. It has, however, now been demonstrated that a slightly acid wort is a favourable medium for the free development of the desirable types of distillery yeasts, but that the growth of brewery yeasts, and especially of bacteria, is very much restricted, if not entirely suppressed, in a "soured" liquid. The acid which is the result of a properly conducted souring is lactic acid, formed by the decomposition of the sugar in the wort, by bacterial action, and according to the equation $C_6H_{12}O_6 = 2C_3H_6O_3$.

For various reasons (one being that in order to restrict the lactic fermentation when sufficient acid has formed it is necessary to heat the soured liquid to a higher temperature than is desirable in the case of the main wort) it is inexpedient to allow the souring process to take place in the main wort. It is usual to make a small mash, prepared on special lines, for the production of the "bub" (German *Hefegut*), as the soured wort is termed. This is allowed either to "sour" spontaneously, or, better, is inoculated with a pure culture of *B. acidificans longissimus*, which for this purpose is undoubtedly the best variety of the lactic acid bacteria. The optimum developing temperature of this organism is about 104° F., but it is better to keep the wort at 122° F., for at the latter temperature practically no other bacteria are capable of development. When the lactification is completed the wort is raised to 165° F. in order to cripple the lactifying bacteria—otherwise souring would go on in the main fermentation—and after cooling to the proper point it is pitched with yeast. When a good crop of the latter is formed the whole is added to the main wort. The beneficial effects of souring are not due to any specific action of the lactifying bacteria, but purely to the lactic acid formed. It has been found that excellent—and in some respects better—results can be obtained by the use of lactic acid as such in place of the old souring process. Some success has also attended the introduction of hydrofluoric acid and its salts as a substitute for lactic acid. Hydrofluoric acid is poisonous to bacteria in doses which do not affect distillery yeasts, and the latter can be cultivated in such a manner as to render them capable of withstanding as much as 0·2% of this acid. Bacteria, apparently, cannot be "acclimatized" in this fashion. Worts treated with hydrofluoric acid produce practically no side fermentation, and it seems a fact that this substance stimulates diastatic action, and thus permits of the use of relatively low mashing temperatures. The yeast employed in British and Irish pot-still and in some patent-still distilleries is still generally obtained from breweries, but it is now generally recognized that—at any rate for the production of industrial alcohol and for "plain" spirit—a special type of yeast such as the so-called "German" yeast, a good deal of which comes from Holland, but which is now also produced in the United Kingdom on a considerable scale, is desirable in the distillery. This variety of yeast, although closely allied botanically to that used in brewing (belonging as it does to the same class, namely *Saccharomyces cerevisiae*), is capable of effecting a far more rapid and far more complete fermentation than the latter. Probably the most widely known and best "pure-culture" distillery yeast is the one called "Species II," first produced in the laboratories of the Berlin Distillers' Association. The optimum working temperature of distillery yeast is at about 81·5° F.; but it would be inexpedient to start the main fermentation at this temperature, as the subsequent rise may be as much as 36°. It is, therefore, usual to pitch at about 80° F., and then, by means of the attemperator, to cool down very slowly until the temperature reaches 60° F. The temperature subsequently rises as fermentation goes on, but should not exceed 85° F. Pot-still malt whisky distillers frequently work at somewhat higher temperatures. Fermentation is carried on until practically all the saccharine matter is converted into alcohol; and when this is the case, the gravity of the mash is about equal to, or even a little below, that of water. In malt whisky distilleries the original gravity of the wort is usually from 1·050 to 1·060, occasionally lower, but in grain and potato distilleries the worts are often made up to a higher gravity. In Germany gravities as high as 1·11 are employed; but in that country "thick" mashes, owing to the method employed to raise the duty, are a matter of necessity rather than of choice.

It will be seen from the above that the employment of malt for the purpose of rendering starch soluble and fermentable leaves a good deal to be desired in regard to both the mashing and fermenting operations in the production of spirit. The use of acid for this purpose is also attended by serious drawbacks inasmuch as a considerable proportion of the starch is converted into "reversion" products which are practically unfermentable and thus considerable caramelization is brought about by the action of the acid. In the case of the production of potable spirits such as whisky, where the alcohol yield is not the only object, and the conservation of a specific flavour is desired, it is doubtful whether any material improvement can be made in this connexion, as it seems probable that part of the flavour may be due to some of the circumstances which from the point of view of alcoholic yield alone are most undesirable. For the production of industrial alcohol, however, and for the preparation of spirit intended to be used in compound potable spirits and liqueurs, these difficulties have now been surmounted. The older methods at the disposal of the distiller have of late years been enriched by the discovery that certain micro-organisms (or rather the enzymes contained in them) possess the power of converting starch into sugar, and also of splitting up saccharine materials into the ordinary products of alcoholic fermentation. It is possible to inoculate a sterilized wort with a pure culture of a micro-organism of this description and subsequently with a pure culture of yeast, and so to avoid all undesirable features of the older processes.

Details concerning the practical application of this discovery will be found below under *Industrial Alcohol.*

Distillation.—The primary object of the distillation of all fermented liquids is that of separating, as far as possible, alcohol from the non-volatile constituents of the wash. In the second place the object of the distiller is to rectify and concentrate the dilute alcoholic liquid obtained by simple distillation. The degree and manner of rectification and concentration vary in accordance with the type of spirit to be produced, and it will be better therefore to discuss methods of distillation under the headings of the different types of spirit concerned.

Whisky.

1. *Scotch Pot-still Whisky.*—The raw material employed in the manufacture of Scotch pot-still whisky is practically without exception malted barley only. The malt is prepared in much the same way as brewery malt, except that it is generally cured (dried) with a peat, or mixed peat and coke, fire. It is to this peat drying that the so-called smoky flavour of most Scotch pot-still whisky is due. The malt is mashed in a mash-tun on lines similar to those obtaining in the brewery, except that the mashing heats are somewhat different. They should be so regulated as to obtain the maximum yield consistent with the preservation of the proper flavour. In order to obtain as high a yield as possible four separate mashes are as a rule made with the same lot of grist, the temperature of each successive mash being somewhat higher than that preceding it. The worts obtained from the first three mashes are united prior to

fermentation. The liquor from the last mash is used as mashing liquor for the next lot of malt. The general scheme of operations subsequent to mashing is illustrated by fig. 7, which depicts the process at one of Messrs Buchanan's distilleries.

After the wort has been drawn off it is run through a refrigerator, and then passes to the wash backs. The latter are large wooden vessels corresponding to the fermenting backs of the brewer. Here the wort is pitched with yeast, the fermentation starting as a rule in the low wines still is termed "spent lees." Both these liquors are run to waste, or where local circumstances make it necessary are destroyed, or modified by means of a purification process. In some cases the solid matter contained is converted into manure. The mixed feints and foreshots contained in the feints receiver are worked up in the subsequent operation, being mixed with the next lot of low wines in the proportion of roughly one third mixed feints and foreshots, and two-thirds low wines. The object of the double distillation as described is in the first place to concentrate the alcohol

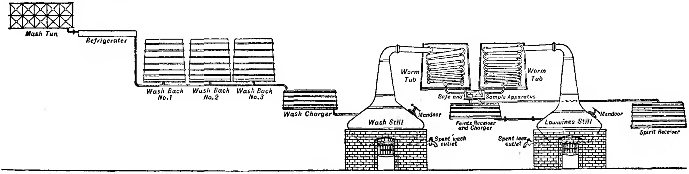

FIG. 7.—Diagram of Malt-whisky Pot-still Plant. (Messrs J. Buchanan's Glentaucher's Distillery, Speyside, N.B.)

at something over 70° F. The maximum temperature attained at some distilleries frequently exceeds 90° F., but in the opinion of the author this is excessive. Fermentation proceeds until the whole of the saccharine matter is converted into alcohol, and when this is the case the gravity of the fermented wort—now termed wash—should be equal to, or a little lower than that of water. The wash from the various wash backs is now collected in the wash charger, which is an intermediary vessel serving for the mixing of the contents of the different wash backs, and also for the purpose of enabling the revenue officer to ascertain the total volume and strength of the wash. In this way he obtains a check on the quantity and gravity of the wort as taken prior to fermentation. From the wash charger the wash passes to the wash still, which is a copper vessel varying in size in Scotland from about 3000 to 8000 gallons. The usual size is about 5000 to 6000 gallons. This still is heated either by direct fire (as shown in the illustration), or frequently by means of a steam jacket or steam coil. The wash still is provided with rakes or chains actuated from outside for the purpose of preventing the solid contents of the wash from being charred. The whole of the spirit is drawn off in one fraction from this still, and is condensed by means of a copper coil cooled by running water. The distillate so obtained is termed "low wines," and the strength is generally about 50 u.p. The next stage in the process is the redistillation of the low wines. This takes place in the low wines still, which is a vessel similar to the wash still, except that it is rather smaller. The distillate from the low wines still is collected in three separate fractions termed respectively and in the order of their collection, (*a*) foreshots, (*b*) clean spirit or whisky, (*c*) feints. The quantity of each of these three fractions collected will vary somewhat according to the nature of the spirit being made, the quality of the material employed, and to other circumstances into which it is not necessary to enter. As a rule the foreshots will be run from the starting of the still down to 25 to 30 o.p. Whisky will be collected from about 25 to 30 o.p. to proof, the remainder, namely the residual fraction, from proof down to water, being feints. In collecting the various fractions the distiller is mainly guided by the alcoholic strength of the spirit coming over, by its flavour, and by its behaviour on mixing with water. It is the object of the distiller to obtain a clean spirit or whisky which gives as little "blueing," that is opalescence, when mixed with water as possible. The foreshots and feints are run into the feints receiver, the whisky to the spirit receiver. The distiller is able to divert the spirit coming over into either of these receivers at will by means of a movable arm contained in the spirit safe. The spirit safe is a closed vessel containing two or more broad funnels each of which is connected with a pipe leading to a feints or spirit receiver as the case may be. The movable arm fixed on to the pipe leading from the condensing coil can be actuated from without by the distiller. In this way the distiller is able to regulate the distillation at will without having access to the spirit. The quality of the spirit coming over is judged by means of the apparatus contained in the sampling safe. This is another closed vessel containing hydrometer jars fitted with hydrometers, and with a water supply. A small part of the spirit coming from the coil passes through this box into the hydrometer jars, where its strength is taken by means of the hydrometers and its behaviour towards water ascertained by mixing with a known volume of the same. The strength of the whisky collected varies at different distilleries, but it is generally from 25 to 30 o.p. The quantity and strength of the spirit are gauged in the spirit receiver by the revenue officer, and the spirit is then run into casks and placed in store. The residue in the wash still is termed "pot ale" or "spent wash," the residue contained in the wash, and secondly to rectify it. Part of the volatile by-products pass out in the spent wash and spent lees; another part is eliminated by the modification which some of these products undergo during storage in the feints receiver.

2. *Irish Pot-still Whisky.*—Both as regards the raw material employed and the manner of manufacture, Irish pot-still whisky differs very appreciably from the Scotch variety. There are a few distillers who work with malted barley only, but the great majority employ a mixture of from (generally) 25 to 50% of malted barley and 50 to 75% of a mixed grist of "raw" (*i.e.* unmalted) rye, wheat, barley and oats. The malt is not peat cured. The distillation is carried out in a type of still radically different from the Scotch pot-still. The stills (of which there are generally three as against two in the Scotch process) are very large, ranging up to 20,000 gallons. A characteristic feature of the Irish pot-still is the great length and height of the "lyne-arm," *i.e.* the pipe connecting the still with the condensing coil. This lyne-arm generally runs up vertically from the still for a distance of 10 to 20 ft., then horizontally for another 30 or 40 ft., again vertically for 10 to 20 ft., and is then connected to the condenser. The horizontal portion of the lyne-arm lies in a shallow trough fitted with a water supply, and the temperature of the spirit vapours prior to their passing to the condenser may thus be regulated at will. According to the length and height of the lyne-arm and the temperature of the water jacket, more or less of the vapours condense and are carried back to the still by means of a pipe running back from the horizontal portion

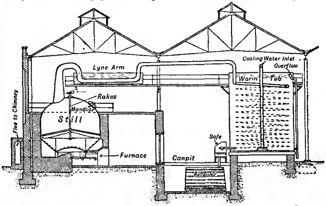

FIG. 8.—Diagram of single type of Irish Pot-still Plant. (Messrs John Jameson's Distillery, Dublin.)

of the lyne-arm to the still. The return pipe is fitted with a cock, which enables the distiller to regulate the return flow. Occasionally there is a further return pipe for the condensing coil, but this is not usual. The result of this form of plant is that it is possible to work up far greater quantities of wash and to obtain a much higher rectification in a single operation than is possible in the case of the Scotch pot-still.

A single type of Irish pot-still plant as employed at Messrs J. Jameson's, Dublin, is shown in fig. 8. It will be noticed that in this case there is no return pipe from the lyne-arm. The method of collection and of working the Irish pot-stills is a great deal more complicated than that described under the Scotch variety. Three stills are employed and strong low wines and weak low wines, strong feints and weak feints are collected, and mixed in varying proportions according to the discretion of the distiller.

3. *American Pot-still Whisky.*—There are two main varieties of American pot-still whisky, namely, rye whisky, in which rye is the predominant raw material, and Bourbon whisky, in which maize or Indian corn is the chief substance employed. There are different varieties of these whiskies.

"Sour mash" whisky is made by scalding the raw material with pot ale (*i.e.* the residue left in the stills from the previous operation), then cooling down to mashing temperature and saccharifying by means of malt. The distillation is sometimes carried out with naked fire, but more generally by means of steam which is passed into the wash (termed "beer" in America), either in a free state or by means of a coil, and then collecting the spirit, after condensing and subsequently rectifying by means of a second distillation (termed "doubling"). "Sweet mash" whisky is made by mashing the raw material in the ordinary way by means of malt. The stills generally employed for making whisky by this procees contain three compartments situated above one another and connected by means of a curve pipe. Live steam blown into the lower compartment causes the wash to boil. The vapours go up through the curved pipe into the next compartment and so cause the contents of the latter to boil. The vapour from the second compartment then passes up to the third in the same manner. The vapour from the third compartment passes into a vessel charged with low wines, and the vapours so obtained are finally condensed, forming whisky, or "high wines."

4. *Patent-still Whisky.*—Scotch and Irish patent-still or "grain" whiskies are manufactured usually with a mixed grist of raw and malted grain, and by means of an apparatus usually termed the "patent," but more properly called Coffey's still. For the manufacture of patent-still whisky a grist containing generally 25% or more of malted barley is employed. The balance consists of maize together with malted and unmalted rye, oats and wheat, and the mixture of grains employed varies at different distilleries. The mashing takes place as a general rule in an ordinary mash-tun, and calls for no special mention. The fermentation is conducted in much the same way as at pot-still distilleries, except that at some patent-still distilleries where bakers' yeast is made it is conducted on somewhat different lines, the conditions being adjusted so as to suit the propagation of a healthy type of yeast of a particular type. For fermentation of this description it is well recognized that the use of selected or pure yeast is necessary. The fermenting vessels, wash chargers, &c., are much the same as in the pot-still distillery except that they are of much larger size. The "patent" still was invented by Aeneas Coffey in the early part of the 19th century with a view of accomplishing in one operation that which necessitates several operations in the pot-still, of economizing time, fuel, and material, and also of obtaining at will a spirit of a higher purity than that which can be got by the pot-still. It is sometimes stated that the patent still does not produce whisky, but merely plain spirit or alcohol, but as a matter of fact this is not the case. It can be so worked by selecting the proper materials and by running the still in a particular way as to produce an article which is most distinctly a potable spirit of the character of whisky. It can also be employed by altering the proportion of the materials and by running the still differently to produce a spirit which may be used for purposes of methylation, or which may pass through the hands of the rectifier and emerge as plain spirit or alcohol pure and simple. It is, however, quite impossible to obtain from the Coffey still a really plain or silent spirit such as that produced by some of the stills on the continent of Europe; in order to obtain this type of spirit the product of the patent still is treated by the rectifier in a special rectifying still with charcoal and potash. In certain details the Coffey still has been modified since it was devised by the inventor, but in principle it has been very little altered. Although it does not in some respects compare with some of the modern continental rectifying stills, it must be remembered that it is not made for the purpose of obtaining pure alcohol, and from this point of view it is a remarkable tribute to the ingenuity of Coffey that he should at so early a date have designed so perfect an apparatus.

The still shown in fig. 9 is one of the type designed by Messrs Robert Willison of Alloa for Scotch grain whisky distilleries. The Coffey still is a double still consisting of two adjacent columns, termed respectively the rectifier and analyser. Both columns are subdivided into a number of chambers by perforated copper plates. The main structure is of wood firmly braced with iron. Each compartment communicates with the next by means of a drop pipe standing slightly above the level of the plate and passing downwards into a cup, which forms a water seal or joint. Each compartment is also fitted with a safety valve in case of the plates choking or of the pressure rising unduly. At the beginning of the operation both columns are filled with steam at a pressure of about 5 lb. The steam at the base of the analyser passes upwards through it, and then to the bottom of the rectifier by means of the pipe B (termed the low-wines vapour pipe), and then up through the rectifier. When both columns are filled with steam the wash is pumped up from the wash charger through the copper pipe A to near the top of the rectifier, which it enters at the point A′. The pipe A runs from the top to the bottom of the rectifier forming a double bend in each compartment, and the wash (contained in the pipe) travels down in a zigzag course until it reaches the base of the rectifier at the point C. From here (still remaining in pipe A) it is pumped to the top of the analyser, where it emerges from the pipe and covers the plate of the top compartment. As there is an upward pressure of steam the wash is not able to pass through the perforations of the copper plate forming the base of the compartment, but collects until its level reaches the top of the first drop pipe. Through this it passes into the cup on the plate below and so out on to the next plate. The drop pipes being trapped by the cups the steam cannot pass upwards through the former. In this way the wash passes through compartment to compartment of the analyser until it reaches the bottom, and then passes out by means of the spent wash siphon. The steam on its passage up through the analyser carried with it the alcoholic vapours and other volatile matters contained in the wash. The alcoholic vapours pass from the top of the analyser to the bottom of the rectifier, and then upwards through the latter from compartment to compartment. In so doing they are gradually cooled by the wash flowing down through the pipe A. This gradual cooling causes the less volatile constituents to condense and so to flow downwards through the column until they reach the base of the rectifier. At a certain point in the upper part of the rectifier (marked S in the illustration) the bottom of the compartment in question is formed not of a perforated plate, but of a stout copper sheet, pierced by a fairly wide pipe, which stands up about two inches above the level of the former. This is termed the spirit plate. It is so placed that the alcoholic vapours condense either on or immediately above it. The alcohol passes out from the spirit plate chamber from one of the two pipes shown in the illustration (either to the spirits or to the feints receiver as the case may be), and is then further cooled, in order to complete the condensation, by means of coils immersed in flowing water, as shown in the illustration. In order to render the condensation still more perfect the upper chambers of the rectifier are fitted with coils through which cold water is passed. The vapours condensed by this fall upon the spirit plate. The vapours which have an appreciably lower boiling-point than ethylic alcohol, such as the aldehydes, together with a large volume of carbonic acid gas derived from the wash, pass out of the top of the rectifier by means of the "incondensible gas" pipe E, and thence to a separate condensing coil. The spirit obtained is of high strength, generally about 64 o.p. The less volatile constituents of the wash, generally termed "fusel oil," which pass out of the base of the rectifier, are cooled and then passed to the oil vessel. After the apparatus has been worked for some time the fusel oil which floats in a layer on the top of the contents of the oil vessel is skimmed off. The watery layer from the oil vessel, which still contains a little alcohol, is again passed through the apparatus to remove the last trace of the latter. By employing the cold wash to cool the alcoholic vapours much condensing water is saved as compared with the ordinary pot-still apparatus. Conversely, as the hot alcohol vapours heat the cold wash to boiling-point, there is a great economy of coal as compared with the older process.

The distillation is controlled by an operator standing on the platform P. The operator is able by means of the sampling apparatus X to determine the quality and strength of the spirit and of the wash. He is able, by regulating the quantity of steam admitted to the apparatus, by modifying the rate of pumping, and by running the spirit either to the spirit or to the feints receiver, as the case may be, to control the strength and quality of the product in much the same manner as does the pot-still distiller.

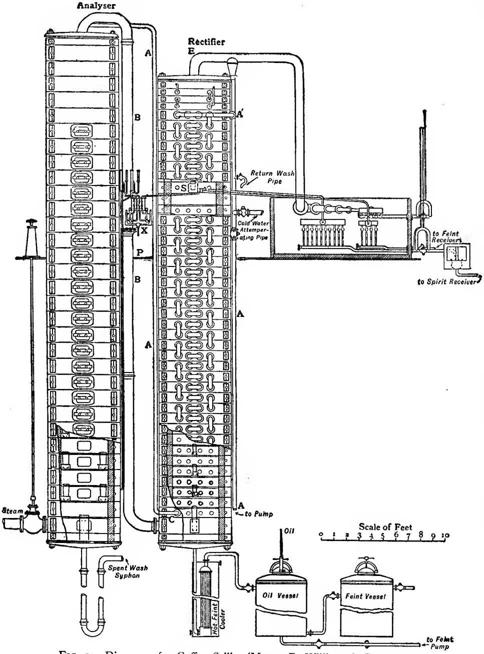

FIG. 9.—Diagram of a Coffey Still. (Messrs R. Willison & Co., Alloa.)

Industrial Alcohol.—By industrial alcohol is understood spirit which is employed for other than potable purposes. Alcohol is largely employed in the industries and arts, and for domestic purposes. It is chiefly used for the manufacture of varnish, fine chemicals and dye-stuffs, for pharmaceutical purposes, and in the form of ordinary methylated spirit for lighting and heating. Ordinary methylated spirit for domestic purposes is prepared in the United Kingdom by adding 10 parts of wood naphtha and a small quantity of mineral naphtha to 90 parts of strong spirit. This spirit may be employed duty free for any purpose, except that it may not be purified in such a manner as to produce pure alcohol or a potable spirit. Up to the year 1906 British manufacturers were forced either to use this spirit or to pay the full duty if they wished to use any other variety. As a result of the recommendations of the industrial alcohol committee of 1904–1905 the Revenue Act of 1906 contained provisions modifying this undesirable state of affairs. Manufacturers may now use a special "industrial methylated spirit," which consists of alcohol 95 parts and wood naphtha 5 parts, and they may also, under certain conditions and restrictions, employ pure alcohol. It is generally considered that the most satisfactory way of methylating or "denaturing" spirit intended for technical purposes is that which consists in adding one of the ingredients which would ordinarily be used in the course of manufacture, or some other ingredient which does not interfere with the manufacture of the specific article in question. In the year 1906 the total quantity of "industrial methylated spirit" employed in the United Kingdom was 2,041,373 proof gallons. The quantity of pure alcohol employed in the same year was 435,915 gallons; for the same period the total quantity of ordinary methylated spirit produced was 6,055,285 gallons. On the continent of Europe and in America alcohol is used in the industries to a greater extent than is the case in the United Kingdom.

The raw materials generally employed in making industrial alcohol are the sugar beet, and beet or cane molasses, potatoes, maize, rice and similar starchy materials. The manufacture of spirit for industrial purposes in many respects resembles the process for manufacturing potable spirit, but, broadly speaking, it may be said that the raw materials employed need not be of so high a class, and that the main object of the distiller in this case is to produce as high a yield of alcohol as possible. Taste and flavour are secondary considerations, although in the case of industrial alcohol employed for some purposes—for instance, for pharmaceutical preparations—a very fine spirit is required. When beets or molasses are employed for making alcohol, the process is a comparatively simple one. If beets are used the sugar is extracted from them in much the same way as is the case in the manufacture of sugar itself (see SUGAR), although in recent years a process for steaming the beets under pressure in much the same way as in the preparation of potato mashes has been employed. The sugar present in the beet and in molasses is not directly fermentable. It is generally rendered so by the addition of a small quantity of mineral acid. The saccharine solution is then pitched with yeast and fermented in the ordinary way. Potatoes, maize, rice and other starchy materials are generally treated under pressure with steam in a close vessel termed a converter. This method entirely disrupts the starch cells, and so renders the starch very readily convertible. When the pressure "cooking" is completed the mash is run out of the converter into the mash tun proper, where it is treated with a minimum quantity of malt at the most suitable temperature. The wort obtained is, after (as a rule) removing a part of the husks and skins by means of special machinery, pitched with yeast and fermented.

We have seen above in the paragraphs dealing with the general features of distillery operations that the method of converting starch into sugar by means of malt possesses very serious drawbacks. Of late years a process has been discovered whereby these disadvantages, as far as industrial spirit is concerned, are entirely overcome. It has been known for some time that certain micro-organisms (or rather the enzymes contained in them) possess the power of converting the starch directly into fermentable sugar, and further of splitting up the latter into the usual products of alcoholic fermentation. Among the organisms of this description first known may be mentioned the moulds, *Aspergillus Oryzae* and *Eurotium Oryzae*. Later A. L. C. Calmette discovered a mould to which he gave the name *Amylomyces Rouxii*, which was employed by A. Collette and A. Boidin for producing alcohol on an industrial scale. Since then Boidin has discovered another mould to which he gave the name of *Mucor* β, which possesses advantages over the other micro-organisms named inasmuch as it works more rapidly and in a more concentrated wort. The amylo process, as this method of producing alcohol is termed, is now worked on a very large scale in many countries. The process consists in inoculating a sterile (mostly maize or rice) mash in a closed vessel with a very small quantity of the spores of the mould, passing filtered air through the liquid for a certain time, thus causing the material to develop very rapidly, and subsequently inducing fermentation by the addition of a pure yeast culture. The mould is of itself capable of fermenting the sugar produced, but it is found that the yeast acts more quickly, and will stand a greater percentage of alcohol, than the former. The whole process occupies about five days. The advantages accruing from operating, as is the case in the amylo process, with sterile worts are enormous, inasmuch as undesirable bacterial and side fermentations are impossible. The quality and yield of the alcohol is, owing to this fact, considerably improved. The fact that no malt is employed leads to a further very considerable economy. The general course of operations in the amylo process may be gathered from fig. 10. The maize or other raw

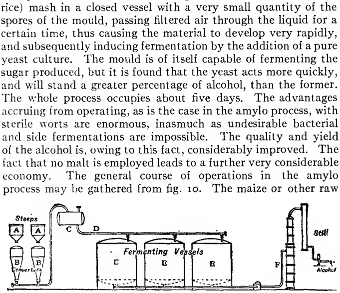

FIG. 10.—Diagram of the Amylo Process.

material is steeped in the vessels AA with a sufficient quantity of dilute acid to convert the secondary into primary phosphates. When the steeping operations are complete the material passes into the converters BB. After conversion is completed the disintegrated material passes into the vessel C, and thence by means of the pipe D to the fermenting vessels EEE. After fermentation is completed the wash passes to the still F.

It is impossible at present to employ the amylo process in its most satisfactory form in the United Kingdom owing to the fact that it is necessary in order to take full advantage of the process to employ a thick wort, *i.e.* one from which the husks have not been removed. The gravity of a wort of this description cannot be taken by the saccharimeter prescribed by the spirit Acts, but no doubt this difficulty will in time be overcome. The average yield by the amylo process is from one to one and a half gallons a cwt. of raw material more than is the case with the processes ordinarily employed in the United Kingdom.

Distillation of Industrial Alcohol.—A still intended for the distillation of industrial alcohol should be so devised as to yield a spirit of the greatest strength and purity in the most economical manner. Stills are now constructed which yield in one operation a spirit containing up to 98% of absolute alcohol, and free from all but the merest traces of aldehyde, fusel oil, &c. (foreshots and tailings). An excellent still of this kind is that of R. Ilges. He takes advantage of the fact that if a liquid containing 15% of alcohol is boiled, the quantity of fusel oil in the vapour is equal to the amount in the remanent fluid, and that if the percentage of alcohol is less than 15% the amount of fusel oil in the vapour is greater than that in the liquid. It is therefore possible, by working on proper lines, to remove the whole of the fusel from the mash by a single operation. By subjecting the vapours so obtained to a carefully regulated dephlegmation, the fusel oil condenses, together with the steam and a certain proportion of alcohol—in practice 15%. By further cooling the liquid so obtained the fusel separates out, and, being specifically lighter, rises to the surface of the watery spirit, and is then easily removed. This form of still is so arranged that any change from the correct temperature necessary for the adequate separation of the concentrated "feints" into two layers is automatically corrected by the admission of more or less cooling liquor to the refrigerating pipe coiled round the dephlegmating column. The "foreshots" (aldehyde, &c.) are removed by submitting the alcoholic vapour passing through the main dephlegmator to further purification. The Ilges apparatus yields three continuous streams of fine spirit, fusel oil, and foreshots respectively.

By-products of Fermentation and Distillation.—The main constituent of spirits is, of course, ethyl alcohol—spirit of wine—but all spirits contain small but varying quantities of by-products and it is by these that the character of a spirit is determined. The by-products are mainly formed during fermentation, but are also to a certain extent pre-existent in the raw materials, or may be formed during the operations preceding and succeeding fermentation. The nature of the by-products is complex, and varies sensibly according to the raw materials employed and the methods of malting, mashing, fermentation and distillation.

The by-products may be classified as follows: (*a*) higher alcohols—usually going under the name of fusel oil; (*b*) esters; (*c*) fatty acids; (*d*) fatty aldehydes and acetals; (*e*) furfuryl aldehyde; (*f*) terpene, terpene hydrate and ethereal oils; and (*g*) volatile bases. The *higher alcohols* consist of mixtures of fatty alcohols ($C_nH_{2n+1}OH$), containing three or more atoms of carbon in which, as a rule, amyl alcohol ($C_5H_{11}OH$) predominates. The fusel oil of British pot-still spirits is chiefly composed of amyl and butyl alcohols, whereas in patent spirits propyl alcohol preponderates, that is, in the finished or fine spirit, since the fusel oil separated from patent spirit in the course of distillation consists mainly of amyl and butyl alcohols. Broadly speaking, the higher alcohols present in pot are of higher molecular weight than those in patent spirits. Potato fusel contains a high proportion of isobutyl alcohol, grain fusel of n-butyl alcohol. The *acid* present in spirits is chiefly acetic acid, but small quantities of other acids are also found. The esters, formed by the interaction of alcohols and acids chiefly during the fermenting and distilling operations, consist almost entirely of fatty acid radicles in combination with ethyl and, to a minor extent, amyl alcohol. Ethyl acetate (acetic ester) is the main constituent of the esters, the others being mainly ethyl valerate, butyrate and propionate. Oenanthic ether (ethyl pelargonate) is one of the characteristic esters of brandy. *Furfuryl aldehyde* (furfurol) is a characteristic product in pot-still spirits, although it occurs to a greater or less extent in patent spirits according to the degree of rectification. It is probable that the furfural is formed by the splitting up of a part of the pentoses contained in the wort. It was formerly thought that its occurrence in relatively large quantities in pot-still spirits was due to the charring effect of the action of the fire gases on the carbonaceous matter adhering to the bottom and sides of the still, but the author has shown that this is not the case, inasmuch as he has found that spirits distilled by means of a steam jacket instead of direct fire contain quite as much furfurol as those distilled in the old way. *Terpene* and *terpene hydrate* are characteristic constituents of grain fusel. Although the *ethereal oils* appear to play an important part in determining the character of a spirit, too little is at present known of these substances to warrant any closer description.

Effect of Maturing on the By-products.—That potable spirits (excepting, of course, pure alcohol) and wine are greatly improved by age is an undeniable fact, and one that has been recognized for many hundreds, and even thousands, of years. Thus in the gospel of St Luke we have the statement "that no man having drunk old wine, straightway desireth new: for he saith, The old is better." And again in the Apocrypha, "New friends are like new wine: when it is old, thou shalt drink it with pleasure." There is little doubt that the beneficial effect of age on the character of spirits is due to the changes effected in the character and quantity of the by-products, but the exact nature of these changes is by no means clear. Such improvement as takes place is apparently connected in some way with the free access of air to, or rather the satisfactory ventilation of, the containing vessel; for spirits preserved entirely in glass undergo relatively little change, either in taste or in chemical composition, whereas cask storage materially affects both these factors.

Concerning the changes which take place during maturation, it was formerly believed that the higher alcohols decreased with age, and that the main reason of the improvement noticeable in mature spirits was due to this fact. The author has, however, shown conclusively that this is not the case, but that on the contrary the higher alcohols generally increase during maturation. This decrease is not absolute, but only relative, and may be due to the fact that the higher alcohols are less volatile than ethyl alcohol. There is a decided increase during maturation of both the volatile and non-volatile acids. On the whole also the esters and aldehydes generally tend to increase, but not to so great an extent as was formerly believed to be the case. There is, however, a marked decrease in regard to furfurol. The type of cask exercises a marked influence on the course of maturation; and, as regards whisky, spirit stored in a sherry cask undoubtedly matures more quickly than that contained in a plain wood cask. The relative humidity of the cellar in which spirit is stored has a very great effect on the course of maturation. In a very damp cellar the spirit will lose alcohol very rapidly and as a result all those changes which are favoured by these conditions will take place with relative rapidity. On the other hand, in a very dry cellar the loss of alcohol is relatively smaller than that of water (cf. Schidrowitz and Kaye, *Journ. Soc. Chem. Ind.*, June 1905).

Physiological Effects of Spirit By-products.—The nature of the physiological effects produced by the ingestion of spirits varies considerably, not only according to the class of spirit (*i.e.* whether whisky, brandy, rum, &c.) consumed, but also with its condition (*i.e.* whether new or old, and so on); and there is no doubt that the causation of these phenomena is intimately connected with the nature and quantity of the by-products, to which, as has been already said, the character of the spirit is due. Commenting on a statement in Bailey's *Book of Sports* to the effect that wine and brandy had a tendency to make a man fall on his side, whisky to make him fall forward, and cider and perry to make him fall on his back, Sir T. Lauder Brunton (*Evidence, Spirits Committee*, 1891) suggests that these statements—if correct—might indicate definite injury to various parts of the cerebellum. Thus, if the anterior part of the middle lobe of the cerebellum is injured, the animal tends to fall forward; when the posterior part is affected, the head is drawn backwards, &c. Brunton is inclined to believe that the varying action of different spirits may be due to the specific action of specific products on the separate nerve centres. Thus the cause of the epileptic convulsions produced by the injection of absinthe has been traced to the specific action of the chief flavouring agent of this liqueur.

In view of the doubt which modern research has thrown on the older theories, to the effect that the improved character of a mature, as compared with a new, spirit is due to the decrease in the quantity of the higher alcohols (*i.e.* the fusel oil), a discussion of the specific action and relative toxicity of these bodies may seem superfluous, more especially as they occur in quantities which are apparently incapable of producing serious effects. As, however, there is considerable reason for believing that the higher alcohols do influence, at any rate, the flavour of the spirit a brief reference to their physiological action seems to the author not out of place. Broadly speaking, the toxicity of the fatty alcohols increases with their molecular weight. Dujar-din-Beaumetz and Audigé found that the lethal dose for dogs was 5–6 grammes per kilo-body-weight for ethyl (ordinary) alcohol; 3·75 grammes for propyl alcohol; 1·8 grammes for butyl; and 1·5 grammes for n-amyl alcohol. It is interesting to note that the experiments of these investigators were conducted chiefly with the pig, as the digestive organs of the latter animal are very similar to those of man, and also because the pig is apparently the only animal which willingly takes alcohol with its food. With regard to the action of spirits generally, the investigators named above found that the digestive organs of pigs fed for thirty months with pure alcohol alone were not affected, whereas the animals treated with similar quantities of imperfectly purified spirit (whether derived from the beet, the potato or from grain) suffered considerably.

Of late years the attention of pharmacologists has been directed to furfurol especially, and the aldehydes generally, as being, at any rate in part, the cause of the unpleasant after or by-effects of certain spirits. Curci and others showed that furfurol in certain doses is poisonous to animals. Brunton and F. W. Tunnicliffe demonstrated a poisonous action of this substance upon man, and, comparing the after-effects upon animals of spirits containing, and freed from, aldehydes, found certain important physiological differences between them. I. Guareschi and A. Mosso first drew attention to the fact that numerous samples of reputedly pure spirits contained small quantities of certain volatile bases of an alkaloidal nature. They apparently belong to the pyridine series, and have effects similar to those of strychnine. E. Bamberger and Einhorn discovered the presence of pyridine, dimethylpyridine and other bodies belonging to the same series, in commercial fusel oil. It is possible that the existence of these volatile bases in spirit may have given rise to the—on the face of it absurd—suggestion that tar bases have been used as adulterants of whisky. It appears likely that the formation of the bases in question is connected with the use of inferior or decaying grain or maize. Thus the spirit produced in Sweden in 1879 was particularly bad and had very curious effects, and it was found, on investigation by M. Husz, that it had actually been largely prepared from decomposing grain. Moreover, C. Lombroso discovered an alkaloidal body in decayed maize, the action of which was not unlike that of strychnine. The quantities of these bases which have been found in spirits are very small, but it must be remembered that substances are known—such as abrine, for instance—which have marked effects in practically unweighable quantities. It is possible that these volatile bases may be responsible for some of the effects—very similar to alkaloidal poisoning—produced by crude spirits such as Cape "smoke" and the cheap Portuguese liqueurs.

Having described the nature and effects of spirit by-products, and the changes occurring in them during storage, the question that arises is: How is the knowledge gained by scientific research in this direction applied in practice? It may be said that the old adage "prevention is better than cure" holds good in the spirit industry as elsewhere, and the distiller, therefore, tries as far as possible to avoid the formation of those by-products which are objectionable, or at any rate to remove them during the course of manufacture. These methods for obtaining a satisfactory potable spirit are so far, however, only successful up to a certain point, and the distiller is therefore bound to have recourse to prolonged storage or to one of the many artificial processes of purification and maturing, the majority of which have been devised—with varying success—during recent years. Referring, in the first place, to what may be called the natural or "preventive" methods for the production of a well-flavoured spirit, it is necessary (*a*) that the water supply (for steeping, mashing, &c.) be a good one; (*b*) that no mouldy or inferior material be used; (*c*) that mashing heats be kept within reasonable limits; (*d*) that refrigerators be constructed so as to avoid bacterial infection; (*e*) that the "souring" of the wort be conducted on proper lines; (*f*) that a favourable and vigorous type of yeast be used; and (*g*) that stills, &c., be kept perfectly clean. Coming next to the methods ordinarily or frequently employed by distillers for eliminating the undesirable by-products, which, despite all care, are formed in the course of manufacture, the most important undoubtedly is purification by rational fractional distillation. By properly regulating the distilling heats, by using a well-devised still, both in the first instance and also for rectifying, a product very free from fusel oil, and especially from fatty aldehydes and volatile ethers, may be obtained. The removal of acids—objectionable chiefly on account of the unpleasant decomposition products which they form in still—is carried out by neutralizing the still contents with an alkaline medium. The alkali so used also decomposes undesirable esters, and retains some of the aldehydes. For the elimination of fusel oil, treatment with charcoal is the most common method. Luck has suggested for this purpose the passing of the alcoholic vapours through petroleum, which is said to absorb the higher alcohols much more easily than it does ordinary spirit; and some distillers have successfully tried the method of V. Traube, which consists in treating the spirit with a saturated aqueous solution of various inorganic salts. This causes the formation of a supernatant layer, which is said to contain practically all the fusel oil as well as the greater part of the foreshot by-products, *i.e.* fatty aldehydes, &c.[1]

Finally, there remain for consideration the *artificial maturing processes*. These are exceedingly numerous, but it may be said at once that the great majority of them are hardly to be taken seriously. Thus one inventor, acting on the alleged fact that spirits are improved by lengthy journeys, suggests that a miniature railway, with numerous obstacles to augment the rolling and shaking action, be laid down in the distiller's warehouse. Of the methods worthy of consideration may be mentioned, first, those depending solely on the action of currents of air, oxygen and ozone. They exist in numerous modifications, but the principle involved, broadly speaking, is to pass a current of hot or cold air or oxygen, or alternate currents of hot and cold air, or a current of ozonized air, through the liquid, with or without pressure, as the case may be. According to the patents of E. Mills and J. Barr, new whisky rapidly acquires the character of the mature sherry-cask stored spirit if the action of alternate hot and cold air currents be assisted by the addition of a little sherry and a minute trace of sulphuric acid, the latter being subsequently neutralized by lime. Secondly, there are the processes which make direct or indirect use of the electric current. Of the indirect methods in this class may be mentioned that of Hermite, which consists essentially in adding an electrolysed solution of common salt to the spirit, and subsequently redistilling. Thirdly, the processes which rely on accelerating natural cask action by artificially reproducing the conditions attendant on the latter in a purposely exaggerated or heightened form. One method strives to obtain this object by heating the spirit under pressure in an atmosphere of oxygen in a vessel containing a quantity of oak shavings. This process certainly seems calculated to remove a portion of the by-products, for the "grog" obtained in A. H. Allen's experiments by steaming the staves of an old whisky cask contained appreciably more fusel oil and esters than commercial whisky. Fourthly, we have the methods chiefly dependent on the action of cold. R. P. Pictet, by cooling a new brandy to −80° C., is said to have obtained a liquid which had apparently acquired the properties of a twelve-year-old spirit. R. C. Scott's process consists in energetically treating spirit which has been cooled down to 0° C. with dry filtered air, and the operations are so conducted, it is said, that there is no loss of alcohol or of the important aromatic esters. According to the published data, the quantity of the fusel oil is materially reduced by this method, and the quality of the spirit much improved. None of the above processes has apparently (although in practice they may give satisfactory results) been devised with a view to effecting the direct removal of those specific substances (furfurol, other aldehydes and volatile bases) which later research has shown to be present to a greater extent in new or inferior spirits than in the matured or superior article, and to some of which, at any rate, owing to their acknowledged toxicity in very small quantities, it is more than reasonable (as Lauder Brunton and Tunnicliffe have pointed out) to suppose that at least a part of the evil effects by drinking new or inferior spirit may be ascribed. In this connexion a patent taken out by J. T. Hewitt is of interest, inasmuch as it deals with the problem of spirit purification on seemingly rational scientific lines. This patent takes advantage of the fact that furfurol and similar aldehydes can be removed from spirits by distillation with phenylhydrazine-sulphonate of soda, which salt forms non-volatile products with the substance in question. (P. S.)

[1] The above chiefly applies to industrial spirit, in the manufacture of which a product which is practically pure alcohol is desired. These methods can only be used to a limited extent by whisky and brandy distillers, for a complete removal of by-products also entails destruction of the spirit's character.

SPIRITUALISM, a term used by philosophical writers to denote the opposite of materialism, and also used in a narrower sense to describe the belief that the spiritual world manifests itself by producing in the physical world effects inexplicable by the known laws of nature. It is in the latter sense that it is here discussed. The belief in such occasional manifestations has probably existed as long as the belief in the existence of spirits apart from human bodies (see Animism; Magic, &c.), and a complete examination into it would involve a discussion of the religions of all ages and nations. In 1848, however, a peculiar form of it, believed to be based on abundant experimental evidence, arose in America and spread there with great rapidity, and thence over the civilized world. To this movement, which has been called "modern spiritualism," the present article is confined.

The movement began in a single family. In 1848 a Mr and Mrs J. D. Fox and their two daughters, at Hydesville (Wayne county), New York, were much disturbed by unexplained knockings. At length Kate Fox (b. 1839) discovered that the cause of the sounds was intelligent and would make raps as requested, and, communication being established, the rapper professed to be the spirit of a murdered pedlar. An investigation into the matter was thought to show that none of the Fox family was concerned in producing the rappings; but the evidence that they were not concerned is insufficient, although similar noises had been noticed occasionally in the house before they lived there. It was, however, at Rochester, where Kate and her sister Margaret (1836–1893) went to live with a married sister (Mrs Fish) that modern spiritualism assumed its present form, and that communication was, as it was believed, established with lost relatives and deceased eminent men. The presence of certain "mediums" was required to form the link between the worlds of the living and of the dead, and Kate Fox and her sister were the first mediums. Spiritualists do not as yet claim to know what special qualities in mediums enable spirits thus to make use of them. The earliest communications were carried on by means of "raps," or, as Sir William Crookes calls them, "percussive sounds." It was agreed that one rap should mean "no" and three "yes," while more complicated messages were—and are—obtained in other ways, such as calling over or pointing to letters of the alphabet, when raps occur at the required letters.

The idea of communicating with the departed was naturally attractive even to the merely curious, still more to those who were mourning for lost friends, and most of all to those who believed that this was the commencement of a new revelation. The first two causes have attracted many inquirers; but it is the last that has chiefly given to modern spiritualism its religious aspect. Many came to witness the new wonder, and the excitement and interest spread rapidly. It should be noted that expectations favourable to the new idea had already been created by the interest in mesmerism and the phenomena of hypnotic trance (see Hypnotism), widely diffused at this time both in America and Europe. It was believed that information about other worlds and from higher intelligences could be obtained from persons in the sleep-waking state. Andrew Jackson Davis (*q.v.*) was in America the most prominent example of such persons; his work, *The Principles of Nature, Her Divine Revelations* (New York, 1847), was alleged to have been dictated in "clairvoyant" trance, and before 1848 his followers were expecting a new religious revelation. Many reputed "clairvoyants" developed into mediums (*q.v.*). The "spiritualistic" movement spread like an epidemic. "Spirit circles" were soon formed in many families. There is very little evidence to show that mediumship arose anywhere spontaneously,[1] but those who sat with the Foxes were often found to become mediums themselves and then in their turn developed mediumship in others. The mere reading of accounts of séances developed the peculiar susceptibility in some persons, while others, who became mediums ultimately, did so only after prolonged and patient waiting.

There seems to have been little practical interest in spiritualism in England till 1852, when its first development took the form of a mania for table-turning (*q.v.*). This seems to have prevailed all over Europe in 1853. In England it was greatly stimulated by the visit of Mrs Hayden, a professional medium from Boston, in the winter of 1852–1853. Daniel Dunglas Home, the next medium of importance who appeared in London, came over from America in 1855; and for many years almost all the chief mediums for physical phenomena known in England came from the United States. It was at Keighley in Yorkshire—where also the first English periodical, the *Yorkshire Spiritual Telegraph*, was published in 1855 and onwards—that spiritualism as a religious movement first made any mark in England; but this movement, though it spread rather widely, cannot be said to have attained at any time very vigorous proportions. It had taken more hold in its original home in the United States of America, and thence it has spread in some degree to most Christian countries. Nowhere, however, has there been much religious organization in connexion with it, and the force of the movement seems to have declined rather than increased.

In the present article it is impossible to give an exhaustive catalogue of the phenomena and modes of communication of modern spiritualism.[2] The greater part of the phenomena may be divided into two classes. To the first belong what may be called the *physical phenomena* (*q.v.*) of spiritualism—those, namely, which, if correctly observed and due neither to conscious or unconscious trickery nor to hallucination or illusion on the part of the observers, exhibit a force acting in the physical world hitherto unknown to science. The earliest of these phenomena were the raps already spoken of and other sounds occurring without apparent physical cause, and the similarly mysterious movements of furniture and other objects; and these were shortly followed by the ringing of bells and playing of musical instruments. Later followed the appearance of lights; quasi-human voices; musical sounds, produced, it is said, without instruments; the "materialization" or presence in material form of what seemed to be human hands and faces, and ultimately of complete figures, alleged to be not those of any person present, and sometimes claimed by witnesses as deceased relatives; "psychography," or "direct writing and drawing," asserted to be done without human intervention; "spirit-photography," or the appearance on photographic plates of human and other forms when no counterpart was visible before the camera to any but specially endowed seers;[3] unfastening of cords and bonds; elongation of the medium's body; handling of red-hot coals; and the apparent passage of solids through solids without disintegration.

The second class of phenomena, which we may call the automatic, consists in table-tilting and turning with contact; writing, drawing, &c., through the medium's hand; convulsive movements and involuntary dancing; entrancement, trance-speaking, and personation by the medium of deceased persons attributed to temporary "possession" (*q.v.*); seeing spirits and visions and hearing phantom voices. This class bears affinity to some of the phenomena of hypnotism and of certain nervous complaints, to certain epidemics of the middles ages,[4] and to phenomena that have occurred at some religious revivals.

In a third class must be placed the cure of disease by healing mediums. This belongs to medical psychology, and cannot well be studied apart from hypnotic treatment of disease, from the now well-recognized power of suggestion (*q.v.*), from "faith cures," "mind cures," "Christian Science" and cures connected with other forms of religious belief (see FAITH-HEALING).

Phenomena falling into the automatic class are much the most common. The investigation of Carpenter on unconscious cerebration and of Faraday on unconscious muscular action[5] showed early in the movement that it was not necessary to look outside the medium's own personality for the explanation of even intelligent communications unconsciously conveyed through table-tilting, automatic writing and trance-speaking—provided the matter communicated was not beyond the range of the medium's own knowledge or powers. And the whole subject of the action of the subconscious personality—the "subliminal self"—has since been more fully worked out by psychologists and notably by F. W. H. Myers.[6] No one conversant with the facts now doubts that what looks like possession or inspiration by an external intelligence may generally be accounted for by subconscious mentation, so that in all cases where no material effects are produced except such as can be attributed to the muscular action of the medium, the evidence for a supernormal interpretation must depend on the content of the communication. Spiritualists maintain that true information is received, which is provably unknown to the medium or other persons present, or which at least is expressed in a manner obviously beyond their powers; and they attribute this to extra-corporeal intelligences. Others, while not going so far as this, admit that the content of the communications does occasionally exceed the medium's knowledge and affords evidence of telepathic communication (see TELEPATHY) between living persons. Probably most persons who have studied the subject would now be inclined to go this length; and there is some evidence, notably in connexion with the trances of an American medium, Mrs Piper,[7] which has convinced some good observers that the hypothesis of occasional communication from deceased persons must be seriously entertained.[8] Recently the Society of Psychical Research has obtained from various persons automatic script affording important new material for investigation and which prima facie supports the spiritualistic hypothesis. Whether or not further study of the scripts of these writers confirms this hypothesis, it cannot fail to throw light on the nature of the intelligence involved. The scripts contain some matter unknown to the writers and in particular show interconnexions with each other not to be accounted for by knowledge normally possessed by the writers.[9]

At no period of the spiritualistic movement has the class of physical phenomena been accepted altogether without criticism. Most spiritualists know that much fraud in connexion with them has been discovered—frequently by spiritualists themselves—and that the conditions favourable to obtaining them are often such as favour fraud. It is with a full knowledge of these difficulties in the way of investigation that they maintain that unmistakably genuine phenomena are of constant occurrence. Many volumes containing accounts of such phenomena have been printed, and appeal is often made to the mass of evidence so accumulated. "No physical science can array a tithe of the mass of evidence by which psychism" (*i.e.* what is usually called spiritualism) "is supported," says Serjeant Cox.[10] But the

[1] It is possible that the family of Dr Phelps were unaware of the "Rochester knockings" when the disturbances began in his house at Stratford, Connecticut, in 1850 (see Capron's *Modern Spiritualism, its Facts*, &c.); but these disturbances, as recorded, have no closer resemblance to the ordinary occurrences at a spiritualistic séance than those which took place at Tedworth in 1661 (see Glanvill's *Sadducismus Triumphatus*) and at Slawensik in 1806 (see Kerner's *Seherin von Prevorst*), and others too numerous to mention.

[2] See the articles on PSYCHICAL RESEARCH; MAGIC; CONJURING; AUTOMATISM; DIVINATION; CRYSTAL GAZING; HYPNOTISM; APPARITIONS; HALLUCINATIONS; HAUNTINGS, &c.

[3] There have been several professional photographers (all detected in fraud sooner or later) who made it their business to take photographs which should contain, besides the normal sitter, representations of deceased friends. For an account of these see *Proceedings of the Society for Psychical Research*, vii. 268.

majority of these accounts have scarcely any scientific value. Spiritualists have, as a rule, sought to convince not by testimony but by ocular demonstration. Yet, if there is not a mass of scientific evidence, there are a number of witnesses—among them distinguished men of science and others of undoubted intelligence —who have convinced themselves by observation that phenomena occur which cannot be explained by known causes; and this fact must carry weight, even without careful records, when the witnesses are otherwise known to be competent and trustworthy observers.

Among proposed normal explanations of these phenomena that of hallucination (*q.v.*), including illusion as to what is seen almost amounting to hallucination, deserves careful consideration. Sensory hallucination of several persons together who are not in a hypnotic state is, however, a rare phenomena outside the séance room and must not therefore be lightly assumed within it; nor is it in most cases a plausible explanation where there is general agreement not only of all the witnesses but of more than one sense as to what is perceived, as distinguished from what is inferred. Nevertheless something of the kind seems occasionally to have happened, especially at some of the séances with Home.[1]

What may broadly be called "conjuring" is a much more probable explanation of most of the recorded phenomena; and in the vast majority of cases the witnesses do not seem to have duly appreciated the possibilities of conjuring, and have consequently neither taken sufficient precautions to exclude it nor allowed for the accidental circumstances which may on any particular occasion favour special tricks or illusions. The experiments of S. J. Davey and R. Hodgson should be studied in this connexion.[2] At a spiritualistic séance the medium has the privilege of failing whenever he pleases and there is seldom any settled programme—circumstances very favourable to deception. As it was put by Mr Stainton Moses, a leading spiritualist and himself a medium, who wrote under the *nom de plume* of "M.A. (Oxen.)": "In 99 out of every 100 cases people do *not* get what they want or expect. Test after test, cunningly devised, on which the investigator has set his mind, is put aside, and another substituted."[3] In other words, the evidence is rarely strictly experimental, and this not only gives facilities for fraud, but makes it necessary to allow a large margin for accidents, mistakes and mal-observation. It may be urged that if none of the phenomena is genuine we have to assume a large amount of apparently aimless trickery in non-professional mediums. But it must be borne in mind that the most excellent moral character in the medium is no guaranteee against trickery, unless it can be proved that he was in no abnormal mental condition when the phenomena occurred; and extraordinary deceptions are known to have been carried on by hysterical patients and others with no apparent motive.

One of the possibilities to be allowed for is that of exceptional muscular endowment or anatomical peculiarity in the medium. For instance, it is not very uncommon to find persons who can make loud sounds by partially dislocating and restoring the toe, knee, or other joints, and some experiments made with the Fox girls in 1851 supported the view that they made raps by this method.

Besides the general arguments for supposing that the physical phenomena of spiritualism may be due to conjuring, there are two special reasons which gain in force as time goes on. (1) Almost every medium who has been prominently before the public has at some time or other been detected in fraud, or what cannot be distinguished from fraud except on some violently improbable hypothesis; and (2) although it is easy to devise experiments of various kinds which, by eliminating the necessity for continuous observation on the part of the investigator, would place certain phenomena above the suspicion of conjuring, there is no good evidence that such experiments have ever succeeded.

Nevertheless there does exist evidence for the genuineness of the physical phenomena which deserves consideration. Count Agénor de Gasparin, in his *Tables tournantes* (Paris, 1854), gives an account of what seem to have been careful experiments, though they are hardly described in sufficient detail to enable us to form an independent judgment. They convinced him that by some unknown force tables could be got to move without contact. The experiments were conducted with his own family and friends without professional mediums, and in some of them he was assisted by M. Thury, professor of physics at Geneva, who was also convinced of the operation of an unknown force.[4] The minutes of the sub-committee No. 1 of the committee of the Dialectical Society (*op. cit.*, pp. 373–391) report that tables moved without contact, whilst all the persons present knelt on chairs (the backs of which were turned to the table) with their hands on the backs. The report, however, would be of greater value if the names of the medium and of the working members of the committee were given—we only know that of Serjeant Cox—and if they had written independent accounts of what they witnessed. Sir William Crookes has published accounts of striking experiments and observations with D. D. Home, which have left him convinced of the genuineness of the wide range of physical phenomena which occurred through Home's mediumship.[5] Of considerable interest again are the experiences of Mr Stainton Moses between 1870 and 1880, of which the best account has been compiled from contemporary records by F. W. H. Myers in two papers published in the *Proceedings of the Society for Psychical Research*.[6] More recently several men of science, including Sir Oliver Lodge in England, Professor Charles Richet in France, and Professors Schiaparelli and Morselli in Italy, have convinced themselves of the supernormal character (though not of any spiritualistic explanation) of certain physical phenomena that have occurred in the presence of a Neapolitan medium, Eusapia Palladino, though it is known that she frequently practises deception.[7] M. Joseph Maxwell, of Bordeaux, has published accounts[8] of raps and movements of objects without contact, witnessed with private and other mediums, which he appears to have observed with care, though he does not describe the conditions sufficiently for others to form any independent judgment about them.

The interest in spiritualism, apart from scientific curiosity and mere love of the marvellous, is partly due to the belief that trustworthy information and advice about mundane matters can be obtained through mediums—to the same impulse in fact which has in all ages attracted inquirers to fortune-tellers. The more thoughtful spiritualists, however, are chiefly interested in the assurance of life and progress after death, and the moral and religious teaching, which they obtain through automatic writing and trance-speaking. It was discovered very early in the movement that the accuracy of these communications could not always be relied on; but it is maintained by spiritualists that by the intelligent exercise of the reason it is possible to judge whether the communicating intelligence is trustworthy, especially after prolonged acquaintance with particular intelligences, or where proofs are given of identity with persons known to have been trustworthy on earth. Such intelligences are not supposed to be infallible, but to have the knowledge of spirit life superadded to their earthly experience. Still the agreement between communications so received has not been sufficiently

great for anything like a universal spiritualistic creed to have been arrived at. In France the doctrine of successive reincarnations with intervals of spirit life promulgated by Allan Kardec (L. H. D. Rivail) forms a prominent element of spiritualistic belief. This view has, however, made but little way in England and America, where the opinions of the great majority of spiritualists vary from orthodox Christianity to Unitarianism of an extreme kind. Probably it would be impossible to unite spiritualists in any creed, which„ besides the generally accepted belief in God and immortality, should postulate more than the progress of the spirit after death, and the power of some of the dead to communicate with the living by means of mediums.

Spiritualism has been accused of a tendency to produce insanity, but spiritualistic sittings carried on by private persons do not appear to be harmful provided those who find in themselves "mediumistic" powers do not lose their self-control and exercise these powers when they do not desire to do so, or against their better judgment. Public sittings are apt to be means of obtaining money by false pretences, and the great scandal of spiritualism is undoubtedly the encouragement it gives to the immoral trade of fraudulent mediumship.

Bibliography.—In addition to the works already mentioned, the student, for a general idea of the whole subject, should consult the following: F. Podmore, *Modern Spiritualism* (2 vols., London, 1902), and *The Newer Spiritualism* (1910); F. W. H. Myers, *Human Personality and its Survival of Bodily Death* (2 vols., 1903); E. W. Capron, *Modern Spiritualism, its Facts*, &c. (Boston, 1855), for the early history of the movement in America; J. W. Edmonds and G. T. Dexter, *Spiritualism* (New York, 1853–1855); R. Hare, *Experimental Investigations of the Spirit Manifestations* (New York, 1856); Allan Kardec, *Livre des esprits* (1st ed., 1853); Mrs De Morgan, *From Matter to Spirit* (London, 1863), with preface by Professor De Morgan; Alfred Russel Wallace, *Miracles and Modern Spiritualism* (1876); W. Stainton Moses [M.A. (Oxon.)], *Spirit Identity and Spirit Teaching*; Zöllner, *Wissenschaftliche Abhandlungen* (the part relating to spiritualism has been translated into English under the title *Transcendental Physics* by C. C. Massey); *Report of the Seybert Commission on Spiritualism* (Philadelphia, 1887); Professor Th. Flournoy, *Des Indes à la Planète Mars* (Geneva, 1900; there is an English translation published in London); *Proceedings of the Society for Psychical Research*, passim. A succinct account of typical frauds of spiritualism is contained in D. D. Home's *Lights and Shadows of Spiritualism* (2nd ed., 1877–1878), and also in Hereward Carrington's *The Physical Phenomena of Spiritualism, Fraudulent and Genuine* (Boston 1907). (E. M. S.)

SPIT, a rotating bar for roasting meat, game or poultry. A spit usually has one or more prongs to which the meat is fixed; in the case of a basket-spit it is enclosed in an oblong basket of iron wire. The old form of spit was fixed on hooks or upon rachets on the fire-dogs; at one end of the bar is a grooved wheel for a chain connected with a smoke-jack in the chimney, or some similar contrivance for turning the spit so that every surface of the meat is exposed to the fire in turn. The jack was sometimes turned by a boy or a small dog trained for the purpose, the boy and the dog were equally known as turn-spits. The spits, when not in use, were placed in a spit-rack over the fireplace. These primitive arrangements eventually gave place to a combined spit and mechanical roasting-jack, which was fixed to a small crane projecting from the mantelpiece. The jack, which was largely of brass, rotated when wound up, and the meat was hung below it immediately in front of the fire, and the gravy and dripping were caught in a large shallow metal pan with a high screen to prevent the diffusion of heat. The almost universal employment in England of closed kitcheners has thrown all forms of spits and jacks into disuse, but in old-fashioned kitchens they are still sometimes seen. The more ancient forms of roasting apparatus are now much sought after by collectors.

SPITALFIELDS, a district of London, England, in the western part of the metropolitan borough of Stepney. The name is derived from the fact that the land belonged to a priory of St Mary Spital, founded in 1197. Excavations have revealed a Roman burial-place here. The name is well known in connexion with the silk industry established here by French refugees after the revocation of the Edict of Nantes, in 1685.

SPITHEAD, a strait of the English Channel, between the mainland (the coast of Hampshire, England) and the north-eastern coast of the Isle of Wight, forming the eastern entrance to Southampton Water, the Solent being the western. Its length is about 12 m., and its general breadth about 4 m., though the distance between Ryde and Gilkicker Point is almost exactly 3 m. The Spit Sand, extending south-east from this promontory, gives name to the strait. On the north side opens the narrow entry to Portsmouth Harbour, with the towns of Portsmouth and Gosport east and west of it. On the south the coast of Wight rises sharply though to no great elevation; it is well wooded, and studded with country residences. Here is also the favourite watering-place of Ryde. Spithead, which as an anchorage is exposed only to the south-east, shares in the fortifications of Portsmouth Harbour, the principal station of the British navy. In this connexion the strait has been the scene of many splendid naval pageants, such as those attendant upon the jubilee in 1897, and the funeral in 1901 of Queen Victoria, and that which celebrated the coronation of King Edward VII. on the 16th of August 1902.

SPITI, an extensive minor division of Kangra district in the Punjab, India. Area, 2155 sq. m., the population (1901) being only 3231, all Buddhists. It consists of an outlying Tibetan valley among the external ranges of the Himalayas, which has a mean elevation of 12,981 ft. and contains on its borders many peaks over 20,000 ft. and one in the outer Himalayas of 23,064 ft. in altitude. Spiti originally formed part of the kingdom of Ladakh, and came into the hands of the British in 1846. The river Spiti rises at the converging angle of the Kamzam and outer Himalayan ranges at a height of 20,073 ft., drains the whole valley of Spiti, and falls into the Sutlej after a course of 120 m.

SPITSBERGEN (the name being Dutch is incorrectly, though commonly, spelled *Spitzbergen*), an Arctic archipelago, almost midway between Greenland and Novaya Zemlya, in 76° 26′ to 80° 50′ N. and 10° 20′ to 32° 40′ E., comprising the five large islands of West Spitsbergen or New Friesland, North-East Land, Edge Island, Barents Island and Prince Charles Foreland, the Wiche Islands, and many small islands divided by straits from the main group. The chief island, West Spitsbergen, shaped like a wedge pointed towards the south and deeply indented on the west and north by long branching fjords, has an area of about 15,200 sq. m. At the north-west angle of the island is a region of bold peaks and large glaciers, in the midst of which is the fine Magdalena Bay. Farther south come the series of glaciers called by the whalers "The Seven Icebergs," which drain a high snowfield reaching east almost to Wood Bay and south to the head of Cross Bay. On the south-east it is drained by glaciers towards or into Dickson and Ekman bays. South of this snowfield comes the mountainous King James Land, consisting of an intricate network of craggy ridges with glaciers between. A deep north-and-south depression is occupied by Wijde and Dickson bays, the one opening on the north coast, the other a head-branch of the great Ice Fjord of the west coast, bordered on the west by a range of fine mountains, a spur of which separates the two bays. East of this depression there is a plateau region. Its edge is eaten away into deep valleys, down which the ice-sheet of New Friesland sends glacier tongues into Wijde Bay. East of Dickson Bay the marginal valleys are larger, and no glaciers come far down them. The plateau between Dickson and Klaas Billen bays is cut up by deep valleys such as the Rendal, Skansdal and Mimesdal (all well known to geologists); it contains no large glaciers. Farther east is found a glaciated area called Garwood Land by Sir Martin Conway. The neck of West Spitsbergen is bounded on the north by a line from near the head of Klaas Billen Bay to Wiche Bay, and on the south by the Sassendal and the depression leading to Agardh Bay. It is a complicated area of fine craggy ridges with beautiful glaciers between. Adventure Land lies south of the neck, and is bounded on the south by a line from the head of Van Keulen Bay to Whales Bay. It is an area of boggy valleys, rounded hills, and small glaciers, and may be described as the temperate and fertile belt, and is the only part of the island where reindeer still linger in any number. Near the west coast it contains some fine peaks and large glaciers. It is penetrated by the longest green valleys in Spitsbergen, *e.g.* from Coles Bay, Advent Bay and Low Sound (the valley of the Shallow river). The southern division of the island is very icy. There is a high snowfield along its east side, and ranges of peaks farther west. Two parallel ranges form the backbone of the island south of Horn Sound, the higher of them containing the famous Horn Sund Tind (4560 ft.). The long narrow island, Prince Charles Foreland, with lofty peaks, runs parallel to part of the west coast of West Spitsbergen, from which it is separated by a narrow strait. Its range of mountains is interrupted towards the southern end of the island by a flat plain of 50 sq. m. raised only a few feet above sea-level. There is a narrower depression a few miles farther north. The broad Stor (Great) Fjord, of Wybe Jans Water, separates the main island from two others to the east—Edge Island (2500 sq. m.) and Barents Land (580 sq. m.). Formerly these were considered as one, until the narrow Freeman Strait which parts them was discovered. Neither Barents Land nor Edge Island carries ice-sheets, and both are practically devoid of glaciers down their western coasts, but have large glaciers reaching the sea on the east. To the north-east of West Spitsbergen, separated from it by Hinlopen Strait (7 to 60 m. in breadth) lies North-East Land, with an area of about 6,200 sq. m. Its western and northern coasts are indented by several bays and fjords. It is covered with a true ice-sheet, while the neighbouring Wiche Islands to the south-east bear no large glaciers at all. East by north from Cape Leigh Smith, the easternmost promontory of North-East Land, rises White Island, covered with snow and ice, and rising to about 700 ft. It was discovered by Cornelis Giles or Gillis in 1707, and is alternatively named Giles Land. Numerous small islands lie around the larger: Danes and other islands off the north-west coast of West Spitsbergen, the Seven Islands, Outger Reps, Broch, and Charles XII. Island on the north of North-East Land; Hinlopen Strait contains numerous islets, and the Ryk Yse Archipelago, Hope or Walrus Island, and the Thousand Islands (about a hundred small rocks) lie to the east and south of Edge Island.

The nomenclature is in a state of hopeless confusion, the names given by the old explorers having been carelessly transferred from point to point, or capriciously set aside. The true names, English and Dutch, of the principal misnamed sites are here indicated in brackets after the current names: South Cape (Point Look-out), Torrel's Glacier (Slaadberg), Recherche Bay (Joseph's Bay, Schoonhoven), Van Keulen Bay (Lord Ellesmere Sound, Sardammer Rivier), Van Mayen Bay (Low Sound, Klok Rivier), Coal Bay (Coles Bay), Advent Bay (Adventure Bay), St John's Bay (Osborn's Inlet), English Bay (Cove Comfortlesse), Foreland Sound (Sir Thomas Smith Bay, Keerwyk), Cross Bay (Close Cove), the bay called Smeerenburg (Fair Haven, Dutch Bay), Flat Hook (Fox Point), Biscayers' Hook (Point Welcome), Redbeach (Broad Bay), Leifde Bay (Wiche Sound), Grey Hook (Castlin's Point), Wijde Bay (Sir Thomas Smith Inlet), Verlegen Hook (Point Desire), Treurenberg Bay (Bear Bay), Agardh Bay (Foul Sound), Stor Fjord (Wybe Jans Water), North-East Land (Sir Thomas Smith Island), North Cape (Point Purchas). Stans Foreland is not, as often appears, an alternative name of Edge Island, but the name of its south-eastern cape only.

Geology.—The backbone of the main island consists of an ancient mass of pre-Devonian granites, gneisses and schists forming a mountain chain in the western region. Resting upon these ancient crystalline rocks, the precise age of which has not been definitely determined, there is a succession of sedimentary rocks representing nearly every one of the prominent periods of geological time. For the eastern part of the group these strata lie nearly horizontal; here and there they are pierced by intrusive igneous rocks. The oldest sediments yet found are the Ordovician beds which occur at Hekla Hook, dolomites, limestones, slates and quartzites; Silurian rocks may possibly exist in the north-west; and Devonian grits with *Pteraspis* have been recorded in Liefde Bay. The Carboniferous period is represented by Culm-like rocks (classed by O. Heer as Ursien—Upper Devonian); upon these come limestones with *Spirifer Mosquensis* (Hinlopen Straits) and above these again are limestones with *Cyathophyllum* and *Fusulina*; (Eisfjord, Bell Sound, Horn Sound, &c.). Permo-Carboniferous limestones and dolomites occur on the west on the mainland and on Prince Charles Foreland and in King James Land. Black slaty shales with large ammonites in the Calcareous nodules and beds of black, bituminous limestone represent the Trias at Cape Thorodsen; and Rhaetic fossils are found in Research Bay, Bell Sound. Jurassic rocks are widely spread and include Bajocian, Bathonian, Callovian, Oxfordian and Portlandian (Cape Starashchin and Advent Bay); the older stages being in the west. Some of these rocks are coal-bearing. Wealden strata with coal seams and marine beds (Volgian) occur in the south, and in King Charles Land are Neocomian rocks with interbedded basalts. Plant-bearing lower Cretaceous strata have been recorded, and lower Eocene beds are found in Ice Fjord, Bell Sound containing large magnolia leaves and others; beds of London Clay age occur in Kolbay. Miocene Sandstones and clay with lignite beds, some 2800 ft. thick, occupy the west coast about Ice Fjord, Bell Sound, Advent Bay, &c. In this period these islands were probably all united and covered a much greater area and were covered with extensive peat bogs, on the edges of which the marsh cypress flowered, dropping its leaves and blossoms into the marshes. *Sequoia*, poplars, birches, planes and large oaks also grew there, while ivy and thick underwood freely developed under their shadow, and thousands of insects swarmed in the thicket. Subsidence followed in late Tertiary times, to be succeeded by a period of rapid elevation giving origin to the raised beaches such as those seen on Prince Charles Foreland, and possibly resubmergence may be again in progress. In comparatively recent geological times this, the main island, was over most of its area a high plateau covered with an ice-sheet, which has gradually been withdrawn from the west towards the east, the western region being thus cut up into deep valleys and more or less rugged mountains. Farther east the mountains are more rounded, but still farther east the plateau character of the land remains.

Climate.—The sea around Spitsbergen is shallow, and the ice readily accumulates round the shores. Although the glaciers of Spitsbergen do not give origin to icebergs so huge as those of Greenland, the smaller bergs and the pack-ice are thick enough to prevent access to the shores except for a few months in the year. However, the warm drift from the Atlantic sends a branch to the western shores of Spitsbergen, moderating its climate, and leaving an open passage which permits vessels to approach the western coast even under the most unfavourable conditions of ice in the arctic regions. Drift-wood from lower latitudes, glass floats of the Norwegian fishermen and other objects have been found at the northern extremity of Spitsbergen. On the other hand a cold current charged with ice descends from higher latitudes along the eastern coasts, rendering approach extremely difficult. On this account these shores long remained practically unknown.

Owing to the warm drift the climate of Spitsbergen is less severe than in the corresponding latitudes of Greenland and Smith Sound. Bear Island, notwithstanding its more southerly position, has a lower temperature. The isotherm of 23° F., which crosses the middle of Eastern Siberia, touches its southern extremity, and only the north-east coasts of Spitsbergen have an average yearly temperature so low as 14° to 10·5°. At Mussel Bay (79° 53′) the average yearly temperature is 16° (January 14·1°, July 39·3°). Even in the coldest months of the winter a thaw may set in for a few days; but, on the other hand, snow sometimes falls in July and August. Spring comes in June; the snow becomes saturated with water and disappears in places, and scurvy grass and the polar willow open their buds. By the end of June the thermometer has ceased to sink below the freezing-point at night; July, August and September are the best months. In September, however, autumn sets in on shore, and by the end of the month the pack-ice rapidly freezes into one solid mass. In Treurenberg Bay an annual precipitation of 64 in. has been observed.

Fauna and Flora.—The Greenland whale has completely disappeared in consequence of the great havoc made by the early whalers. According to Scoresby, no less than 57,590 whales were killed between 1669 and 1775. A great diminution, in the same way, is to be observed in the numbers of other creatures which were the object of hunters. A reckless extermination of seals was carried on. Walruses are now only occasionally seen in the waters of West Spitsbergen. Birds, also, have rapidly diminished in numbers. The fulmar petrel meets ships approaching Spitsbergen far away from the coasts. It makes colonies on the cliffs, as also do the glaucous gull and the "burgomaster." Rotches, black guillemots, ivory gulls, auks and kittiwake gulls breed on the cliffs, while geese, looms and snipe frequent the lagoons and small fresh-water ponds. The eider duck breeds on the islands, but its numbers have become noticeably reduced, while the lumme and the tern confine themselves to separate cliffs. These birds, however, are only guests in Spitsbergen, the snow-bunting being the only species which stays permanently; some twenty-three species breed regularly on Spitsbergen, and four others (the falcon, snowy owl, swan and skua) come occasionally. Of land mammals, besides the polar bear, the reindeer and arctic fox have been greatly reduced; the reindeer, in fact, are approaching extinction, whereas for several years consecutively before 1868 from 1500 to 2000 were killed by hunters in a few weeks of summer.

There are twenty-three species of fishes, but no reptiles. Insects are few. Arachnids, and especially Pantopods, on the other hand, are very common. Molluscs are also numerous. At some places the mussels and univalves reach a large size and appear in great abundance. Of Crustaceans fully 100 species have been recognized in the waters of the archipelago.

The flora is, of course, poor. The only tree is the polar willow, which does not exceed 2 in. in height and bears a few leaves not larger than a man's finger-nail; and the only bushes are the crowberry and cloudberry. But at the foot of the warmer cliffs some loam has been formed notwithstanding the slowness of putrefaction, and there, in contrast with the brownish lichens that cover the hills, grows a carpet of mosses of the brightest green, variegated with the golden-yellow flowers of the ranunculus, the large-leaved scurvy grass, several saxifrages, fox-tail grass, &c., with a few large flowers, *Polygona* and *Andromedae*; while on the driest spots yellow poppies, whitlow grasses, &c., are found. Even on the higher slopes, 1500 ft. above the sea, the poppy is occasionally met with. In all over 130 species of flowering plants have been found. Mosses, mostly European acquaintances, cover all places where peat has accumulated. The slopes of the crags and the blocks of stone on the beach are sometimes entirely covered with a luxuriant moss and lichen vegetation, among the last being the so-called "famine bread" (*Umbilicaria arctica*), which has maintained the life of many arctic travellers. Although limited in number, the flora is suggestive in its distribution. The vegetation of the south has a decidedly Lappish or European alpine character, while that of the north coast is decidedly American, and recalls that of Melville Island. Many flowering plants which are common in north-west Spitsbergen are absent from the east coast, where the cold climate is inimical to both flora and fauna; but, on the other hand, one moss (*Pottia hyperborea*) and one lichen (*Usnea melaxantha*) are found there which are of American origin and grow both in North America and on the Cordilleras. Algae are most numerous, many, like the brown *Laminaria* and *Nostoc communis*, which fill all pools and are the chief food of many birds, being familiar in Europe. *Protococcus nivalis* covers the snow with its reddish powder.

History.—Spitsbergen has never been permanently inhabited, although there are several instances of hunters wintering on the island under stress of circumstances, and several scientific expeditions have done so. A Russian trapper named Starashchin is said in various accounts to have spent 32 or 39 winters, and 15 consecutive years, in the archipelago; he died there in 1826. Spitsbergen was discovered on the 17th of June 1596, during the expedition under William Barents and Jacob Heemskerk, which ended with the death of Barents. Barents saw parts of the west and north coasts, and to these he gave the name of Spitsbergen. In 1607 Henry Hudson, after visiting the coast of Greenland, reached Spitsbergen in June. Bear Island, the ice-bound island midway between Spitsbergen and the North Cape, situated on the same submarine platform as the former, had been discovered by Barents, and became important as a hunting-ground (for walrus, &c.) before Spitsbergen began to be visited for this purpose. In 1609 Thomas Marmaduke of the "Heartsease," proceeding north from Bear Island, reached Spitsbergen, and in the following year the first hunting expedition was despatched thither by the Muscovy Company on board the "Amitie" of London, Jonas Poole, master, on whose report of the abundance of whales on the coast the Spitsbergen whaling industry, which was to grow to such importance, was established in 1611. Very shortly the Dutch began to take a share in this, and there were frequent collisions between the whalers of the two nationalities, while in 1615 the Danes attempted to claim this part of "Greenland," as Spitsbergen was for a long time considered. England attempted to annex the archipelago, but at length the Dutch became predominant in the whaling industry, and in 1623 founded the summer settlement of Smeerenburg. This became a busy and important centre, but began to decline in about twenty years, as the whales were gradually driven from the bays and must be followed, at first northward along the coast, and later into the open sea. Independently of the English and Dutch, Russians from the White Sea district came to Spitsbergen to hunt walruses, seals, bears, foxes, &c. At what early period they first did so cannot be known, but the industry seems to have gained a certain importance before 1740. The Russians had their own nomenclature for various parts of the archipelago, the whole of which they also called Grumant, a corruption of Greenland. A similar hunting industry was established by Norwegians early in the 18th century, but Spitsbergen declined in importance as a hunting-ground owing to the indiscriminate slaughter of game.

Many expeditions have made Spitsbergen their base for polar exploration. The Russian admiral Chichagov visited it twice, in 1765 and 1766, and reached 80° 28′ N. The expedition sent from England in 1773 at the instigation of Daines Barrington under the command of Constantine John Phipps, was the first having a purely geographical purpose. It consisted of two vessels, the "Racehorse" and the "Carcass," on the first of which Horatio Nelson was a midshipman. Phipps mapped the north of Spitsbergen, and reached 80° 48′ north. In 1818 David Buchan and John Franklin reached 80° 34′ to the north of the archipelago. Captain D. C. Clavering and Sir Edward Sabine in 1823 explored the islands, and Sabine made his remarkable magnetic observations, while Clavering reached 80° 20′ N. Sir William Parry, shortly after his return from his third voyage, went to Spitsbergen and reached 82° 40′ north on sledges, while other members of the expedition were occupied with scientific work in the archipelago. In the same year the Norwegian geologist Balthasar Mathias Keilhau visited the group and related his experiences in a remarkable book, *Resa i Ost og West Finmarken* (Christiania, 1831). The Swedish professor Sven Loven was the first to undertake, in 1837, dredging and geological explorations in Spitsbergen and its vicinity. Next year a body of French, Swedish, Danish, and Norwegian naturalists, among whom was Charles Martins, visited the western coast. In 1858, at the suggestion of Loven, Otto Torell, accompanied by A. E. Nordenskiöld and A. Quennerstadt made many important observations and brought home rich geological collections. In 1861 a larger expedition led by Torell, Nordenskiöld, A. J. Malmgren, and Karl Chydenius, set out with the object of finding how far it was possible to obtain a measurement of an arc of meridian of sufficient extent. This aim was only partly accomplished, but the expedition returned with an invaluable store of various observations. The work of the measurement of the arc was completed in 1864 by another expedition conducted by Nordenskiöld, assisted by Malmgren and N. Dunér. This expedition was followed in 1868 by that of the "Sofia," under Nordenskiöld, which, in the words of Oswald Heer, "achieved more and gave a wider extension to the horizon of our knowledge than if it had returned merely with the information that the 'Sofia' had hoisted her flag on the North Pole." In the same year the German arctic expedition under Karl Koldewey circumnavigated West Spitsbergen. In 1870 two young Swedish savants, Drs Nathorst and Wilander, visited Spitsbergen in order to examine the phosphoric deposits, and two years later a colony was formed in Ice Fjord, and a small tramway constructed to work the beds. The attempt, however, did not prove successful. Leigh Smith and the Norwegian Captain Ulve visited and mapped parts of East Spitsbergen in 1871, returning with valuable information. They reached 81° 24′ north. In the same year the first tourist steamer visited the archipelago. In 1872 a great polar expedition under Nordenskiöld set out to winter on Spitsbergen with the intention of attempting in the spring to advance towards the pole on sledges drawn by reindeer. But the expedition encountered a series of misfortunes. The ships were beset in the ice very early in Mussel Bay, and, six Norwegian fishing vessels having been likewise overtaken and shut in, the expedition had to feed the crews on its provisions and thus to reduce the rations of its own men. The reindeer all made their escape during a snow-storm; and when the sledge party reached the Seven Islands they found the ice so packed that all idea of going north had to be abandoned. Instead of this, Nordenskiöld explored North-East Land and crossed the vast ice-sheet which covers it. The expedition returned in 1873 with a fresh store of important scientific observations, especially in physics and submarine zoology. In 1873 R. von Drasche-Wartinberg, the geologist, paid a short visit to Spitsbergen, In 1882 the Swedish geologists, A. G. Nathorst and G. de Geer made a journey which furnished interesting data about the geology and flora of the islands. In the same year a Swedish meteorological station was established at Cape Thordsen for carrying on the observations desired by the international polar committee. During the last decade of the 19th century Spitsbergen attracted not only a number of scientists but also sportsmen and tourists. Such expeditions as those of Gustaf Nordenskiöld in 1890 and the important circumnavigation by Nathorst in 1898, during which the Wiche Islands and White Islands were carefully explored, confined their attentions almost entirely to the coasts. In 1892 M. C. Rabot made the first serious attempt to penetrate the interior from the head of Ice Fjord, exploring a part of the Sassendal; and in 1896 Sir Martin Conway led an expedition which crossed the island for the first time, and surveyed the region between Ice Fjord and Bell Sound on the east coast. In 1897 Conway and Mr E. J. Garwood surveyed the glaciated area north of Ice Fjord to about 78° 10′ N., and climbed Horn Sund Tind. In the same year Herr André made his fatal balloon ascent from Danes Island with the intention of floating over the Pole. In 1896 a weekly service of Norwegian tourist steamers was established in summer, and a small inn was built at Advent Bay in Ice Fjord, and though this was afterwards closed, the west coast continued to be frequently visited by tourist steamers during the height of summer. In 1898, 1899 and 1906 the prince of Monaco made scientific investigations in the Archipelago, and in 1898–1902 Swedish and Russian expeditions undertook the measurement of an arc of the meridian, the results of which were accompanied by valuable physiographical, meteorological, botanical and other observations. Dr W. S. Bruce made a complete survey and scientific investigations of Prince Charles Foreland. In 1900 coal began to be worked on Advent Bay, a seam 10 ft. thick being found below 40 ft. of fossil ice and 20 ft. of rock. This development and other considerations led to some discussion between the powers interested as to the territorial sovereignty over the archipelago, a question which though approached before (as in 1870) had never been brought to a settlement.

BIBLIOGRAPHY.—On a land visited by so many scientific observers the literature is naturally voluminous. The chief source of scientific papers is the publications of the Swedish *Vetenskaps Akademie.* Sir W. Martin Conway narrates his expedition in the *First Crossing of Spitsbergen* (London, 1897); and in *No Man's Land* (Cambridge, 1906) he details the history of the Archipelago down to 1840, tabulates the principal voyages and incidents thereafter until 1900, and furnishes a very full bibliography for the history and geography of Spitsbergen from the earliest time down to 1902. The various observations of the Swedish expedition for the measurement of an arc of the meridian were brought together (in French) in *Missions scientifiques pour la mesure d'un arc de méridien au Spitzberg* . . . (Stockholm, 1903–1906), and those of the Russian expedition under the same title in 1904, seq. (St. Petersburg).

SPITTA, FRIEDRICH (1852–), German Protestant theologian, was born at Wittingen on the 10th of January 1852. His father, Karl Johann Philipp (1801–1859), well known as a hymn-writer (see *Lyra domestica*, 1st series, London, 1860; 2nd series, 1864), was superintendent at Burgdorf near Hanover. Friedrich studied at Göttingen and Erlangen, and in course of time became (1887) professor ordinarius and university preacher at Strassburg. In 1896 he became joint-editor with J. Smend of the *Monatschrift für Gottesdienst und kirchliche Kunst*, and he is widely known as the author of a work on the Acts of the Apostles (*Die Apostelgeschichte, ihre Quellen und deren geschichtlicher Wert* (1891).

His other works include: *Der Knabe Jesus, eine biblische Geschichte und ihre apokryphischen Entstellungen* (1883), *Die Offenbarung des Johannes* (1889), *Zur Reform des evang. Kultus* (1891), and *Zur Geschichte und Litteratur des Urchristentums* (3 vols., 1893–1901).

SPLEEN (Gr. σπλήν), a vascular organ situated on the left side of the abdomen (see DUCTLESS GLANDS). It was supposed in olden times to be the seat of ill-humour and melancholy, whence such phrases as "to have the spleen," to be out of temper, sulky, morose, "splenetic."

SPLÜGEN PASS, one of the passes across the main chain of the Alps from Switzerland to Italy (from 1512 to 1797, however, Chiavenna belonged to the Grisons). The route quits that of the Albula Pass (*q.v.*) at Thusis, passes first through the celebrated gorge of the Via Mala, then through the Schams basin and past Andeer, beyond which the Rofna gorge gives access to the village of Splügen (from which the pass takes its name) in the upper reach of the main or Hinter branch of the Rhine (*q.v.*). Leaving to the west the road over the San Bernardino Pass, 6769 ft. (by which the St Gotthard railway line is joined at Biasca, the route lying entirely through Swiss territory) the Splügen road (constructed in 1823) mounts south to the pass (6946 ft.), which forms the political frontier. On the other side the road avoids the old path through the dreaded Cardinello gorge (here passed Macdonald's army in December, 1800) in order to descend by zigzags to Pianazzo. Thence past Campo Dolcino and Gallivaggio the descent is made to the ancient town of Chiavenna at the junction of the road from the upper Engadine over the Maloja Pass, and 17 m. by rail above Colico, at the northern end of the lake of Como. The distance by road from Splügen village (16 m. above Andeer) to Chiavenna is 25 m. The diligences take $5\frac{1}{2}$ hours from Splügen village (4 hours above Thusis) to Chiavenna. But by the proposal to pierce a railway tunnel of about 16 m. in length from Andeer to Gallivaggio, it was calculated that the Splügen line would become the shortest route from southern Germany to Milan, while at Chiavenna it would receive the traffic from the upper Engadine. (W. A. B. C.)

SPODUMENE, a lithium-aluminium silicate belonging to the pyroxene group (see PYROXENE). It was named by B. J. d'Andrada e Sylva, in 1800, from Gr. σπόδιος (ash-coloured), in allusion to its grey colour. Soon afterwards J. R. Haüy termed it *triphane*, because it exhibited certain characteristics equally in three directions (τριφανής, appearing three-fold). Spodumene crystallizes in the monoclinic system, the crystals having generally a prismatic habit and being often striated longitudinally. It has perfect prismatic cleavage, and imperfect cleavage parallel to the clinopinacoid, whilst a lamellar structure may be developed by parting along the orthopinacoid. The hardness is 6·5 to 7, and the specific gravity about 3·16. Though generally a dull mineral, some varieties of spodumene are so brightly coloured and transparent as to be valued as gem-stones. Such is the emerald-green hiddenite (*q.v.*) and the lilac-coloured kunzite (*q.v.*), whilst a yellow or yellowish-green spodumene found as pebbles in the state of Minas Geraes, in Brazil, resembles, when cut, some kinds of chrysoberyl. Common spodumene is used as a source of lithium in chemical preparations.

Spodumene occurs in granite and crystalline schists. The original specimens came from the isle of Utö in Södermanland, Sweden, but the finest examples are found in the United States, especially in Massachusetts, where Goshen, Sterling and Chesterfield are well-known localities. Very fine specimens have been obtained from the Black Hills of S. Dakota. Some remarkable deposits containing spodumene were discovered many years ago at Branchville, Fairfield county, Connecticut, and the minerals which they yielded were exhaustively studied by Professor G. J. Brush and E. S. Dana. The spodumene occurred in large quantity, in a vein of albite-granite, associated with apatite, garnet, columbite, pitchblende and other uranium minerals, together with several species of manganese phosphates, termed eosphorite, triploidite, dickinsonite, lithiophilite, natrophilite, reddingite, fairfieldite and fillowite. The spodumene, which has normally the formula $LiAl(SiO_3)_2$, becomes altered at Branchville to what has been called β-spodumene, which consists really of the mineral eucryptite ($LiAlSiO_4$) and albite. Eucryptite was named by Brush and Dana from εὖ (well) and κρυπτός (concealed). Further alteration results in the formation of cymatolite, a mineral described by C. U. Shepard in 1867, but shown to be an intimate mechanical mixture of muscovite and albite. The final products of alteration of the spodumene may be muscovite, albite and microcline. The mineral discovered in 1817 in the granite of Killiney Hill, near Dublin, and described by T. Thomson as killinite, appears to be an altered spodumene. (F. W. R.*)

SPOHR, LUDWIG (1784–1859), German composer and violinist, was born at Brunswick on the 25th of April 1784. He spent his childhood at Seesen, where in 1789 he began to study the violin, and at six years old was able to take part in chamber-music. He had a few lessons in composition, but, as he himself tells us, he learnt more from studying the scores of Mozart. After playing a concerto of his own at a school concert with marked success, he was placed under Maucourt, the leader of the duke's band; and in 1798 he started on an artistic tour. This proved a failure; but on his return to Brunswick the duke gave him an appointment in his band, and provided for his future education under Franz Eck, with whom he visited St Petersburg and other European capitals. His first violin concerto was printed in 1803. In that year Spohr returned to Brunswick and resumed his place in the duke's band. A visit to Paris was prevented by the loss of his favourite violin—a magnificent Guarnerius, presented to him in Russia. After a series of concerts in Berlin, Leipzig, Dresden, and other German towns, his reputation gained for him in 1805 the appointment of leading violinist to the duke of Gotha. Soon after this he married his first wife, Dorette Scheidler, a celebrated harpist. At Gotha he composed his first opera, *Die Prüfung*, but did not succeed in producing it. *Alruna* was equally unfortunate, though Goethe approved of it at a trial rehearsal at Weimar in 1808. In this year Spohr, hearing that Talma was performing at Erfurt before Napoleon's Congress of Princes, and failing to obtain admission to the theatre, bribed a horn-player to send him as his deputy; and, though he had never touched a horn in his life, he learned in a single day to play it well enough to pass muster in the evening and so to get a good view of Napoleon and the princes in a pocket mirror on his desk. Spohr's third opera, *Der Zweikampf mit der Geliebten*, written in 1809, was successfully performed at Hamburg next year. In 1811 he produced his (first) *Symphony in E flat*, and in 1812 composed his first oratorio, *Das jüngste Gericht*.[1] In writing this work he felt hampered by lack of skill in counterpoint; so with characteristic diligence he mastered the contents of Marpurg's *Abhandlung von der Fuge*.

In 1812 Spohr visited Vienna, and was induced to accept the leadership of the orchestra at the Theater an der Wien. He then began his dramatic masterpiece, *Faust*, which he completed in 1813, though it was not performed until five years later. His strength and inventiveness as a composer were now fully developed, and enabled him to produce large works with astonishing rapidity. He resigned his appointment at Vienna in 1815, and soon afterwards made a tour in Italy, where he performed his eighth and finest violin concerto, the *Scena cantante nello stilo drammatico*. The leading Italian critics called him "the finest singer on the violin that had ever been heard." On Spohr's return to Germany in 1817 he was appointed conductor of the opera at Frankfort; and there in 1818 he first produced his *Faust*. It was followed by *Zemire und Azor*, which, though by no means as fine as *Faust*, soon attained a much greater popularity. *Faust* suffered from its libretto, which is on quite a different plot from Goethe's poem.

Spohr first visited England in 1820, and on the 6th of March played his *Scena cantante* with great success in London at the first Philharmonic concert. At the third he produced a new symphony (*No. 2 in D minor*) and, instead of having it led by the first violinist and a *maestro al cembalo*, conducted it himself with a bâton; a great innovation in London at the time. Spohr had a triumphant success both as composer and as virtuoso; and he on his side was delighted with the Philharmonic orchestra. At his farewell concert in London Mme Spohr played on the harp for the last time. The constrained attitudes of harp-playing were bad for her health; so in later concerts she played the pianoforte in duets with violin which her husband produced with his usual prompt facility. After a transitory visit to Paris, Spohr returned to Germany and settled for a time in Dresden, where German and Italian opera were flourishing side by side under the direction of Weber and Morlacchi. Spohr could not appreciate Weber's genius; nevertheless Weber recommended him strongly to the elector of Hesse Cassel as Kapellmeister. Spohr entered upon his duties at Cassel on the 1st of January 1822, and soon afterwards began his sixth opera, *Jessonda*, which he produced in 1823. This work—which he himself regarded as one of his best—marks an important epoch in his operatic career. It was his first opera on Gluck's lines, *i.e.* with accompanied recitative throughout in place of secco-recitative or spoken dialogue; and it was produced in the same year as Weber's *Euryanthe*, a work marked by the same departure from German custom.

Spohr's resources at Cassel enabled him to produce his new works on a grander scale and with more perfect detail than he could have attained in a less well-endowed post; and he never failed to use these privileges to the advantage of other meritorious composers, though as a critic he was very difficult to please. Soon after his instalment Mendelssohn, then a boy of thirteen, visited Cassel; notwithstanding the disparity of their years, a firm friendship sprang up between the two, which ceased only with Mendelssohn's death in 1847. Spohr's next three operas, *Der Berggeist* (1825), *Pietro von Abano* (1827) and *Der Alchymist* (1830), attained only fair temporary success. But at the Rhenish musical festival held at Düsseldorf in 1826, his oratorio *Die letzten Dinge* met with so enthusiastic a reception that it was repeated a few days later in aid of the Greek Insurgents, and became the most famous of his sacred compositions. It is known in English as *The Last Judgment*. In 1831 Spohr summed up another aspect of his career by publishing his *Violin School*, an admirable book for advanced students, which stands to the violin much as the combination of Cramer's *Studies* with Clementi's *Gradus* stands to the pianoforte. The year 1834 was saddened by the death of Spohr's wife. In 1836 he married again. During 1833 he had been working at an oratorio—*Des Heilands letzte Stunden*, known in English as *Calvary* or *The Crucifixion*—which was performed at Cassel on Good Friday 1835, and sung in English at the Norwich Festival of 1839 under Spohr's own direction, with an effect which he afterwards always spoke of as the greatest triumph of his life. For the Norwich Festival of 1842 he composed *The Fall of Babylon*, which also was a perfect success, though the elector of Hesse-Cassel, unmoved by a petition from England almost amounting to a diplomatic representation, refused Spohr leave of absence to conduct it. His last opera, *Die Kreuzfahrer*, was produced at Cassel in 1845. Of his nine symphonies the finest, *Die Weihe der Töne*, was produced in 1832. His compositions for the violin include concertos, quartetts, duets, and other concerted pieces and solos, and among these a high place is taken by four double quartetts, (*i.e.* octets for two antiphonal string-quartet groups), an art-form of his own invention. He was, indeed, keenly interested in experiments, notwithstanding his attachment to classical form; and the care with which he produced Wagner's *Fliegender Holländer* and *Tannhäuser* at Cassel in 1842 and 1853, in spite of the elector's opposition, shows that his failure to understand Beethoven lay deeper than pedantry. Spohr retained his appointment until 1857, when, very much against his wish, he was pensioned off. In the same year he broke his arm, but he was able to conduct *Jessonda* at Prague in 1858. This, however, was his last effort. He died at Cassel on the 16th of October 1859.

Spohr's *Selbstbiographie* is a delightful document, revealing a character the generosity of which was conspicuous through all its complacent intellectual foibles. He was a born taste-maker, for he mastered the technique of his art safely and then applied his mastery to the expression of exactly those modes of thought which surprise no one who believes that each art-problem has one answer and that the critics know it. But he had a very genuine melodic invention, and his sense of beauty was such as even the all-pervading mannerisms of his otiose chromatic style could not quite destroy. He tried every experiment the copy-book optimism of his age could suggest; the subjects of his operas are all that is romantic and necromantic; he wrote almost as much "programme-music" as Berlioz; he invented

[1] Not to be confused with *The Last Judgment*.

"double quartets," he wrote an *Historical Symphony* tracing the progress of music from Bach to his own day; and, lastly, his gift for orchestration was quite exceptional. Yet not one of his experiments shows any essential connexion between the new form and the old material which he has so skilfully packed into it. Nor is his treatment of his beloved classical forms any nearer to organic life. In conversation with Joachim he once in his last years expressed the ambition to write a set of string quartets "in the strict form with all the passages ending properly with shakes." This shows that all his work as a composer had failed to wean him from the conventions of virtuoso players, and it well illustrates the way in which "strict forms" desert their convenient functions to pose as classical ideas; for the "passage ending in a shake" is merely the easiest known way of finishing a section in concerto style, and is so far from being an essential feature in chamber-music that in the ten mature quartets of Mozart which Spohr undoubtedly regarded as his models it cannot be traced in more than twelve of the thirty one movements in which it ought to occur.

The steady level of Spohr's mastery prevents any of his work from either rising to the height of Mendelssohn's masterpieces, or sinking to the weakness of Mendelssohn's failures. But where the true conditions of an art-form suit Spohr's training and temperament he is, at times, very nearly a great composer; and in the severely restricted medium of duets for two violins his work is an artistic *tour de force*, the neglect of which would be unfortunate in a wider field than that of mere violin-technique. His best work is not so great that we are obliged to live with it; but its merits demand that we should let it live. (D. F. T.)

SPOIL-FIVE, an old game of cards, probably imported from Ireland, where it is still very popular, though the original name, according to *The Compleat Gamester*, was "Five-cards." It may probably be identified with "Maw," a game of which James I. of England was very fond. A full pack of cards is used: about five players is the best number, each receiving five cards, dealt in pairs and triplets, the card that is left at the top of the pack being turned up for trumps. If the turn-up is an ace, the dealer must "rob," *i.e.* put out, face downwards, any card from his hand and take in the ace. The trump suit remains unaltered. "Robbing" must take place before the first player, the player on the dealer's left, leads. Similarly a player who *holds* the ace of trumps must rob, putting out any card and taking in the turn-up, but need not disclose the fact till it is his turn to play. A player who fails to rob cannot go out that hand. The card put out may not be seen. The player on the dealer's left leads. The highest card of the suit led—the value of the cards will be explained—or the highest trump, wins the trick. Players must follow suit to a lead of trumps, except in certain cases which will be mentioned. To a plain suit no one need follow except a player who holds no trumps; others may follow or trump as they please. If a player takes three tricks he wins the game. If no one succeeds there is a "spoil," and a fresh stake, smaller than the original one as a rule, is put into the pool for the next round. The order of the cards in plain suits may be remembered by "after the knave the highest in red and the lowest in black." In red suits the order is king, queen, knave, ten, &c., down to the ace, which is lowest: in black suits king, queen, knave, ace, &c., up to ten, which is lowest. But the ace of hearts, which is always a trump, is not reckoned in its own suit. In trumps the order is "below the queen highest in red, lowest in black." The order in red suits is five, knave, ace, of hearts, ace of trumps, king, queen, ten, &c.: in black suits five, knave, ace of hearts, ace of trumps, king, queen, two, three, &c., up to ten, which is the lowest. When trumps are led, the five and the knave of trumps and the ace of hearts need not be played. This is called "reneging," colloquially "renigging." The five may always renege: if it is led, no card can renege. The knave may renege if the five is played, not led. Only the five can renege to the knave led. The ace of hearts can renege to any inferior card. If hearts are not trumps and the ace of hearts is led, a trump must be played if possible: if not, it is not necessary to play a heart. "Twenty-five" and "Forty-five" are varieties of "Spoil-five": the game is played for either of these numbers; each trick counts five to the maker, and there is no "spoil," but the trick made by the highest trump out scores ten; if a player gets out before that trump is played, he wins the game all the same. The winning of all five tricks is called a "jink"; at "Spoil-five" a player who jinks, if jinking is agreed upon, receives an extra stake all round; but if, after winning three tricks, he elects to "jink" and fails, he cannot score during that hand.

SPOKANE, a city and the county-seat of Spokane county, Washington, U.S.A., on both banks of the Spokane river, near the eastern boundary of the state, and about 242 m. E. of Seattle. Pop. (1890), 19,922; (1900), 36,848, of whom 7833 were foreign-born, including 1683 English Canadians, 1326 Germans, and 1168 Swedes; (1910 census) 104,402. Spokane is served by the Great Northern, the Oregon Railway & Navigation Co. (Union Pacific system), the Northern Pacific, the Idaho & Washington Northern, the Spokane, Portland & Seattle, and the Spokane & International railways, and by the Spokane & Inland Empire (electric) line connecting with the Cœur d'Alêne mining region, Idaho, and with Colfax, Washington and Moscow, Idaho. Among the principal buildings of the city are the Federal building, the county court-house, the city-hall, the post office, the Paulsen building, the Columbia and Auditorium theatres, the Spokane club, the masonic temple, the Spokesman-Review building, and a large Roman Catholic church. Spokane is the see of a Protestant Episcopal bishop. The city has a Carnegie library, and ten public parks aggregating 320 acres; the more important are Liberty Park (25 acres), Manito Park (85 acres), and Corbin Park (13 acres). Fort George Wright (established in 1895) is 3 m. west of Spokane on a tract of 1022 acres given to the United States Government by the city, for that purpose, in 1894–1895. Spokane is the seat of Gonzaga College (Roman Catholic) for boys, founded in 1887 and incorporated in 1904; of Spokane College (1907; Lutheran); of Brunot Hall (Protestant Episcopal), for girls; the Academy of the Holy Names (Roman Catholic), for girls; and of other schools and academies. Among the city's charitable institutions are a home for the friendless (1890), the St Joseph orphanage (1890), St Luke's (1900) and the Marie Beard Deaconess (1896) hospitals, each having a training school for nurses, a Florence Crittenden home, and a House of the Good Shepherd. The Spokane river is a rapidly flowing stream with two falls (the upper of 60 and the lower of 70 ft.), within the city limits, providing an estimated energy of about 35,000 horse-power at low water. Of this energy, in 1908, about 17,000 horse-power was being utilized, chiefly for generating electricity (the motive power most used in the city's industries), as well as for lighting and transit purposes, while about 9000 horse-power in electrical power was transmitted to the Cœur d'Alêne mines. At Post Falls, Idaho, 22 m. east of Spokane, about 12,000 horse-power is developed, and at Nine Mile Bridge near Spokane, about 20,000 horse-power. Spokane's manufacturing interests have developed with remarkable rapidity. In 1900 there were 84 factories capitalized at $2,211,304, and their product was valued at $3,756,119. In 1905 there were 188 factories capitalized at $5,407,313 (144·5% increase), and the value of their products was $8,830,852 (135·1% increase). The city's principal manufactures in 1905 were: lumber and planing mill products ($2,040,059); flour and grist-mill products ($1,089,396); malt liquors ($679,274); foundry and machine-shop products ($479,954); and lumber and timber products ($418,019). Spokane is an important jobbing centre, is a natural supply point for the gold, silver and lead mining regions of northern and central Idaho, eastern Washington, and Oregon, and is a distributing point for the rich agricultural districts in this region.

The first permanent settlement on the site of Spokane was made in 1874 by James N. Glover, who bought from two trappers a tract of land here. The settlement was named Spokane Falls, in memory of the Spokan Indians, a tribe of

Salishan stock, which formerly occupied the Spokane Valley; the word Spokan is said to mean "children of the sun." Spokane was incorporated as a town in 1881 and in the same year received its first city charter (amended in 1891). The city became the county-seat in 1882. The present name was adopted in 1890. The city was reached by the Northern Pacific railway in 1883, by the Union Pacific in 1889, and by the Great Northern in 1892. On the 4-6th of August 1889, thirty squares of the city (nearly all of its business section) were destroyed by fire, with a loss estimated at $5,000,000. Rebuilding was at once begun, and in about two years the city had been almost entirely reconstructed and greatly improved. In 1910 Spokane adopted a commission form of government.

SPOLETO (anc. *Spoletium*), a town and archiepiscopal see of the province of Perugia, Italy, 18 m. N.N.E. of Terni, and 88 m. N. by E. of Rome by rail. Pop. (1901), 9631 (town); 24,648 (commune). It is situated on a hill, so that the lowest part is about 1000, the highest 1485, ft. above sea-level, at the south end of the open valley of the Topino, a tributary of the Tiber, which it joins near Assisi. The principal industries are the collection and preparation of truffles and preserved foods, also tanning and the manufacture of earthenware. Spoleto is also the centre of an agricultural district, and contains a government experimental olive oil factory. There are few towns of Italy which possess so many Roman remains in good preservation under the medieval buildings, and few medieval towns with so picturesque an appearance. There are considerable remains of perhaps pre-Roman polygonal walls—in one place a piece of this walling has masonry of rectangular blocks superposed, with an inscription of two of the Roman municipal magistrates (*quattuorviri*). There are also a few traces of an inner enceinte of the Roman period. There are remains of a Roman theatre, over 370 ft. in diameter, and an amphitheatre 390 by 205 ft. A Roman bridge of three arches, 80 ft. long and 26 ft. high, exists at the lower (north) entrance to the town, under the modern road to Foligno, in the former bed of a torrent which has now changed its course. A Mithraeum was found outside this gate in 1878. The rock above the town was included within the polygonal walls: but Totila fortified, not this rock, but the amphitheatre, which remained the citadel until 1364, when Cardinal Albornoz destroyed it and erected the present Rocca, which was enlarged by Pope Nicholas V.; it is now a prison. The Porta della Fuga (the name alludes to the repulse of Hannibal) occupies the site of a Roman gate, but is itself medieval: while the medieval enceinte encloses a somewhat wider area than the ancient. The Piazza del Mercato represents the Roman forum; close by is a triumphal arch of Drusus and Germanicus, and a temple (?) into which is built the church of S. Ansano. A Roman house in the upper part of the town, with mosaic pavements, probably belonged to Vespasia Polla, the mother of the emperor Vespasian. The Palazzo Municipale, close by, contains the archives and picture gallery. The cathedral of S. Maria Assunta, much modernized in 1644, occupies the site of a church of the Lombard dukes erected about 602. The present church was consecrated in 1198; the façade belongs to the middle of the 12th century. Over the main entrance is a large mosaic of Christ enthroned, with the Virgin and St John, by the artist Solsernus (1207). The Early Renaissance vestibule (after 1491) is fine. In the choir and on the half dome of the apse, are the finest frescoes of Fra Filippo Lippi (scenes from the life of the Virgin) completed after his death by Fra Diamante: his tomb, erected by Lorenzo de' Medici, with the epitaph by Politian, is on the left of the choir. The fine stalls and panelling in the winter choir date from 1548–1554. In and near the Piazza del Duomo are the unfinished Palazzo della Signoria, of the early 14th century, which contains the archaeological museum, the small Renaissance church of the Manna d'Oro (1527), the façade of the Romanesque basilica of S. Eufemia (in the archbishop's palace) and the fine Early Renaissance Palazzo Arroni with its graffito frieze.

The church of S. Pietro, outside the town on the road to Rome (wrongly supposed to have been the cathedral before 1067), was founded in A.D. 419 by Bishop Achilles. Its façade is remarkable for its richly sculptured decorations of grotesque figures and beasts, which are of two different dates, about 1000 and about 1200. S. Domenico is a fine example of later Italian Gothic with bands of different coloured stones. Both the church and its crypt contain 14th-century frescoes. The triple-apsed crypt of S. Gregorio probably dates from the 9th century: the upper church was consecrated in 1196 and the Romanesque work covered with stucco in the restoration of 1597. S. Nicolò is a beautiful example of Pointed Gothic. The basilica of S. Salvatore (*il Crocefisso*) at the cemetery belongs to the 4th century A.D. The fine sculptures of the façade, with its beautiful windows, as also the octagonal dome, all belong to this period; Meliorantius, the sculptor of the portal of the cathedral (after 1155), took his inspiration hence. S. Ponziano, not far off, belongs to the 13th century, but its interior has been restored: the crypt contains frescoes of the 15th century. The city is still supplied with water by an aqueduct, to which belongs the huge bridge called the Ponte delle Torri, crossing the ravine which divides the town from the Monte Luco (2723 ft.). The bridge is 253 ft. high and 755 ft. long and has ten arches: the ground plan is Roman; the stone piers are in the main later (the work is often attributed to Theodelapius, the third Lombard duke, in 604), while the pointed brick arches belong to a restoration of the 14th (?) century. The Monte Luco, which commands a splendid view, has several hermitages upon it.

The first mention of Spoletium in history is the notice of the foundation of a colony there in 241 B.C. (Liv. *Epit.* xx.; Vell. Pat. i. 14), and it was still according to Cicero (*Pro Balb.* 21)—"colonia latina in primis firma et illustris"—a Latin colony in 95 B.C. After the battle of Trasimenus (217 B.C.) Spoletium was attacked by Hannibal, who was repulsed by the inhabitants (Liv. xxii. 9). During the Second Punic War the city was a useful ally to Rome. It suffered greatly during the civil wars of Marius and Sulla. The latter, after his victory over Crassus, confiscated the territory of Spoletium (82 B.C.). From this time forth it was a *municipium*. Under the empire it again became a flourishing town, but is not often mentioned in history. It was situated on a branch of the Via Flaminia, which left the main road at Narnia and rejoined it at Forum Flaminii. An ancient road also ran hence to Nursia. Martial speaks of its wine. Aemilianus, who had been proclaimed emperor by his soldiers in Moesia, was slain by them here on his way to Rome (A.D. 253), after a reign of three or four months. Rescripts of Constantine (326) and Julian (362) are dated from Spoleto. The foundation of the episcopal see dates from the 4th century. Owing to its elevated position it was an important stronghold during the Vandal and Gothic wars; its walls were dismantled by Totila (Procop. *Bell. got.* iii. 12). Under the Lombards Spoleto became the capital of an independent duchy (from 570), and its dukes ruled a considerable part of central Italy. Together with other fiefs, it was bequeathed to Pope Gregory VII. by the empress Matilda, but for some time struggled to maintain its independence. In 1155 it was destroyed by Frederick Barbarossa. In 1213 it was definitely occupied by Gregory IX. During the absence of the papal court in Avignon it was a prey to the struggles between Guelphs and Ghibellines, until in 1354 Cardinal Albornoz brought it once more under the authority of the Church. In 1809 it became capital of the French department of Trasimene. In 1860 it was taken by the Italian troops after a gallant defence. Giovanni Pontano, founder of the Accademia Pontaniana of Naples, was born here.

See A. Sansi, *Degli Edifizi e dei frammenti storici dell' antichità di Spoleto* (Foligno, 1869), and other works; G. Angelini Rota, *Spoleto e Dintorni* (Spoleto, 1905); and various articles by G. Sordini, in *Notizie degli Scavi.* (T. As.)

SPON, JACQUES (1647–1685), French doctor and archaeologist, was born at Lyons and died at Vevey. He is famous as a pioneer in the exploration of the monuments of Greece, travelling there in 1675–1676 with the Englishman (Sir) George Wheler

(1650–1723), whose collection of antiquities was afterwards bequeathed to Oxford University. Spon brought back many valuable treasures, coins, inscriptions and manuscripts, and in later years published various important works on archaeology, notably his *Voyage d'Italie, de Dalmatie, de Grèce et du Levant* (1678), and a *Histoire de la république de Genève* (1680).

SPONGES. The Sponges or Porifera form a somewhat isolated phylum (or principal subdivision) of the animal kingdom. This phylum includes an immense number of marine and fresh-water organisms, all of which agree amongst themselves in possessing a combination of important structural characters which is not found in any other animals. Though the phylum is a very large one yet almost the only examples with which the name "sponge" is popularly associated are the common bath sponges (species of the genera *Euspongia* and *Hippospongia*), which are amongst the most highly organized and least typical members of the group.

The history of the group begins with Aristotle, who recognized several different kinds of sponge, some of which were used by the Greek warriors for padding their helmets. Owing, however, to the permanently fixed character, irregular growth and feeble power of movement in the adult organism, it was not until the advent of microscopical research that it was definitely proved that the sponges are animals and not plants. Indeed our scientific knowledge of the group can scarcely be said to begin much before the middle of the 19th century, when the classical researches of R. E. Grant, J. E. Gray, H. J. Carter and J. S. Bowerbank laid the foundations of modern spongology. It very soon became evident that the group is one which illustrates with remarkable clearness and beauty those laws of organic evolution which were beginning to attract so much attention from zoologists, a fact which found abundant recognition in Ernst Haeckel's epoch-making work on the Calcareous Sponges published in 1872. This was followed by a series of remarkable researches by F. E. Schulze on the minute anatomy, histology and embryology of the group, which have served as a pattern to all subsequent investigators. In more recent years our knowledge of the sponges has advanced very rapidly, especially as the result of the great series of scientific exploring expeditions inaugurated by the voyage of H.M.S. "Challenger." The large collection made by the "Challenger" expedition alone, necessitated a complete reorganization of our systematic knowledge of the phylum, and afforded the foundation upon which our present system of classification has been built up. There is perhaps no great group of the animal kingdom in the study of which greater advance has been made in the last twenty years. It is impossible in the space at our disposal to do justice to the numerous valuable memoirs which have appeared during this period, but reference to the more important works of recent investigators will be found in the bibliography at the end of this article, while for a comprehensive account of the whole subject the reader should refer especially to Professor E. A. Minchin's article in Sir E. Ray Lankester's *Treatise on Zoology*.

General Characters of the Phylum.—The sponges are all aquatic organisms, and for the most part marine. They vary in size from minute solitary individuals, scarcely visible to the naked eye, up to great compound masses several feet in circumference, and in form from almost complete shapelessness to the most exquisite and perfect symmetry. The indefiniteness of shape and size which characterizes the vast majority of the group is due to the power of budding, which is almost universal amongst them, whereby extremely complex colonies are built up in which it is usually impossible to determine the limits of the individual zooids or persons, while very frequently, by a process of integration, individuals of a higher order are produced which again form colonies by budding (fig. 2).

The entire body of the sponge is penetrated by a more or less complicated canal-system, beginning with numerous inhalant pores, scattered over the general surface or collected in special pore-areas, and ending in one or several larger apertures, the vents or oscula, situated usually on the uppermost portions of the sponge (fig. 8). If the living animal be kept under observation it will be seen that a stream of water is ejected with considerable force from the vents, carrying with it minute particles in suspension. At the same time numerous smaller streams enter the canal system through the inhalant pores, bringing with them the minute particles of organic matter upon which the sponge feeds and the oxygen which it requires for respiration. This stream of water may be temporarily interrupted by the closure of the pores and vents, to be resumed apparently at will. It is maintained by the activity of certain cells, known as collared cells or choanocytes (fig. 35, *g*, fig. 36), which line the walls of the canal system either throughout their entire extent or in certain regions only. These cells bear an extraordinarily close resemblance to the choanoflagellate Protozoa or collared Monads. Each is provided with a filmy protoplasmic collar and a long whip-like flagellum, and the movements of the latter drive the water out of the canal-system through the vents and thus keep up the circulation. In all but the simplest sponges the collared cells are confined to certain portions of the canal system known as flagellated chambers (fig. 9), the size, form and arrangement of which vary greatly in different types. That part of the canal-system which is not lined by collared cells is covered with a flattened pavement-epithelium (fig. 34, 1), and so also is the outer surface of the sponge. The space between the various branches of the canal-system is occupied by a gelatinous ground-substance (mesogloea) in which amoeboid and connective-tissue cells are embedded (fig. 34, 3, 4, 5; fig. 35, *a*), and in which in most cases a well-developed skeleton is secreted by special cells known as scleroblasts. This skeleton (figs. 24–32, &c.) supports the extremely soft tissues of which the body is composed, and consists either of mineral spicules (carbonate of lime or silica) or of horny fibres (spongin), or of a combination of siliceous spicules with spongin. In many cases the proper skeleton is more or less completely replaced by sand.

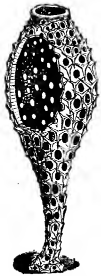
The question as to how far the cell-layers of the sponge body correspond to the "germinal layers" usually recognizable in other multicellular animals is an extremely difficult one and not yet by any means settled. It has until recently been generally supposed that the flattened epithelium which covers the outer surface of the sponge, together with part of that which lines the canal-system, is ectodermal, while the collared cells and the remainder of the flattened epithelium lining the canal-system are endodermal, and the term mesoderm has been frequently applied to the middle gelatinous layer. Recent embryological research, however, makes it extremely doubtful whether this view is justifiable, and whether indeed the germ-layers of typical Metazoa can be identified at all in the Porifera. Embryological research, moreover, tends to show that the primitive gastral epithelium (of collared cells) is in most sponges completely replaced, except in the flagellated chambers, by an invasion of the dermal epithelium (composed of flat pavement-cells).

Sexual reproduction, by means of ova and spermatozoa, is probably universal throughout the group. The segmentation of the ovum gives rise to the free-swimming ciliated larva (figs. 38, *e*, 39) in the form of a hollow "amphiblastula" or of a solid "parenchymula." This larva becomes attached and, by means of a more or less complex metamorphosis, gives rise to the young sponge. During the metamorphosis the outer, ciliated or flagellated cells of the larva take up their position in the interior of the body and give rise to the collared cells of the adult; while the inner cells (of the parenchymula) migrate outwards and form the superficial epithelium, so that the position of the so-called "ectoderm" and "endoderm" is completely reversed in the adult as compared with the larva.

A sexual reproduction is effected by budding, and the buds may either remain attached to the parent and form colonies or become detached and form entirely separate individuals.

Types of Structure.—We may illustrate our account of the general characters of the group by a brief description of the anatomy of three widely divergent types, selected as being fairly representative of the entire group, viz. *Leucosolenia*, *Plakina* and *Euspongia*.

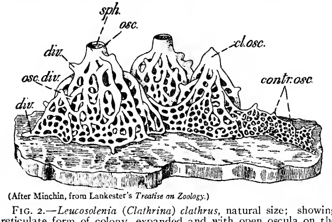
Leucosolenia.—The genus *Leucosolenia* includes a number of calcareous sponges of very simple structure, and thus forms a suitable starting-point for our studies. Imagine a minute, thin-walled sac (fig. 1), attached at the lower end to some rock or seaweed, and enclosing a spacious cavity in its interior. This cavity is the gastral or digestive cavity, and it opens to the exterior through a wide vent or osculum at the upper extremity of the sponge. The thin wall is also pierced by numerous small inhalant pores or prosopyles. The inhalant pores, the gastral cavity and the vent constitute the canal-system, through which a stream of water can be kept flowing by the activity of the collared cells which line practically the whole of the gastral cavity. Each collared cell consists of an oval nucleated body surmounted by a filmy protoplasmic collar, in the middle of which the whip-like flagellum projects into the water. They are placed close together, side by side, and thus form a continuous layer, extending almost up to the vent and interrupted only by the inhalant pores. The outer surface of the sponge is covered by a single layer of flattened pavement-epithelium or epidermis. Some of these cells, distinguished as porocytes, become perforated by the inhalant pores, around which they form contractile diaphragms capable of opening and closing, and thus regulating the supply of water. Between the outer protective, dermal epithelium, and the inner gastral epithelium of collared cells, lies the mesogloea, a layer of gelatinous material containing cells of at least two kinds, amoebocytes and scleroblasts. The former closely resemble the amoeboid white blood corpuscles, or leucocytes, of higher animals, and have the power of wandering about from place to place in the sponge-wall. They probably serve to distribute food material and carry away waste products, and some of them undoubtedly give rise to the ova and spermatozoa. The scleroblasts are derived from cells of the dermal epithelium which migrate inwards into the gelatinous ground-substance and there secrete the spicules of which the skeleton is composed. These spicules are composed of transparent crystalline carbonate of lime (calcite), and may be of three fundamental forms: triradiate, quadriradiate and monaxon. It has been shown by E. A. Minchin, however, that the triradiate and quadriradiate types are not simple spicules but spicule-systems, each formed of three or four primary spicules, originating from as many mother-cells and only secondarily united. In fig. 1 only triradiate spicules are represented, but very often all three kinds are present in the same sponge (cf. fig. 24). The triradiates lie in the mesogloea with their three rays extended in a plane parallel to the surfaces of the sponge-wall, and form a kind of loose scaffolding upon which the soft tissues are supported. The quadriradiates resemble the triradiates in form and position, but a fourth ray is developed which projects through the layer of collared cells into the gastral cavity, where it serves as a defence against internal parasites. The monaxon spicules have one end embedded in the mesogloea while the other projects outwards and upwards and serves as a defence against external foes.



(After Haeckel.)

FIG. 1.—*Leucosolenia primordialis* (Olynthus form).

Although all species of the genus *Leucosolenia* agree essentially in structure, yet they exhibit very great diversity in external form. This is due to the habit of budding and colony formation. All start life after the metamorphosis of the larva in the simple sac-shaped condition which we have just described, and to which the name "Olynthus-type" is sometimes applied. This is indeed the simplest type of sponge organization known to us and we must look upon the Olynthus as representing a primary sponge-individual or "person." By a simple process of budding, in which the buds all remain united together by their bases, we get a branched colony in which the persons or zooids are still easily recognizable, each with its own vent or osculum. Very frequently, however, the zooids become elongated into slender cylindrical tubes which branch in an extremely complex manner and anastomose with one another in many places to form networks, in which it is no longer possible to recognize the component individuals (fig. 2). This is known as the "Clathrina" type of structure, and we may look upon a Clathrina colony as an individual of a higher order, which may assume a definite external form and even acquire a secondary internal cavity (pseudogaster), opening to the exterior through a secondary vent (pseudosculum), while the outer tubes of the colony may give rise to a protective skin (pseudoderm), perforated by secondary inhalant pores (pseudopores) which are obviously quite distinct in nature from the primary inhalant pores or prosopyles of the Olynthus.



(After Minchin, from Lankester's *Treatise on Zoology*.)

FIG. 2.—*Leucosolenia* (*Clathrina*) *clathrus*, natural size; showing reticulate form of colony, expanded and with open oscula on the left, contracted and with closed oscula on the right.

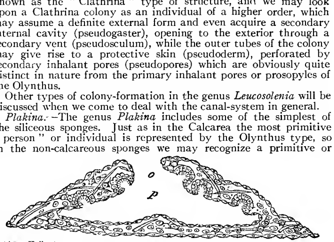
cl. osc, Closed osculum.	*div*, Diverticula.
contr. osc, Closed oscula in contracted part of colony.	*osc. div*, Diverticula from which new oscula arise.

Other types of colony-formation in the genus *Leucosolenia* will be discussed when we come to deal with the canal-system in general.

Plakina.—The genus *Plakina* includes some of the simplest of the siliceous sponges. Just as in the Calcarea the most primitive "person" or individual is represented by the Olynthus type, so in the non-calcareous sponges we may recognize a primitive or fundamental form of individual to which the name "Rhagon" has been applied. This is the first stage reached after the metamorphosis of the larva in certain species, and the little sponge consists of a cushion-shaped sac, attached below by a broad flattened base and terminating above in a single vent or osculum (fig. 3). There is a large gastral cavity lined by pavement-epithelium and surrounded by a number of more or less spherical "flagellated chambers," lined by collared cells. These chambers open into the gastral cavity by wide mouths (apopyles) and communicate with the exterior by smaller inhalant pores. The entire outer surface of the sponge is covered with pavement-epithelium and there is a well-developed mesogloea which may contain spicules. This Rhagon may be compared to an Olynthus which has become flattened out from above downwards and from which a number of small buds (the flagellated chambers) have been given off all round, except from the attached basal portion; so that the whole forms a small colony, in which the collared cells have become restricted to the buds. We may, therefore, perhaps, look upon the Rhagon as an individual or person of a higher order than the Olynthus. Like the Olynthus the Rhagon occurs as a transient stage in the development of certain sponges, but we do not know any non-calcareous sponge which remains in such a simple condition throughout life. In *Plakina monolopha*, for example, the entire wall of the Rhagon becomes thrown into folds (fig. 4) so that a system of inhalant and exhalant canals is formed between the folds, through which the water has to pass on its way to and from the chambers. The inhalant canals lead down between the folds from the outer surface of the sponge. In *P. monolopha* they are wide and ill defined. In another species, *Plakina dilopha*, they become constricted to form perfectly definite, narrow canals, by the development of a thick layer of mesogloea (and pavement-epithelium) which covers the outer surface of the sponge in such a manner that the folded character is no longer visible externally. The external openings of the inhalant canals now form definite dermal pores. In such a sponge as this the folded chamber-layer of the sponge-wall is sometimes called the choanosome, while the external layer of mesogloea and pavement-epithelium is called the ectosome. In a third species, *Plakina trilopha*, further folding of the "choanosomal lamella" takes place and we thus get a still more complex canal-system.



(After Keller.)

FIG. 3.—Vertical section of a Rhagon, diagrammatic. *o*, Osculum; *p*, Gastral cavity.

In *Plakina* the spicules are composed of colloidal silica. The fundamental spicule form is the primitive tetract or calthrops, consisting of four sharp-pointed rays diverging at equal angles from a common centre (fig. 5, *a–e*). Modifications of this form occur in two directions: in the first place some of the tetracts, by branching of one ray, give rise to "candelabra," while others, by suppression of rays, give rise to forms with three or even two rays only, triacts and diacts, the latter sometimes termed oxeate (fig. 5, *f–l*). The arrangement of the spicules is very irregular; the candelabra alone are definitely arranged (at the surface of the sponge). the other forms are thickly scattered without any sort of order throughout the mesogloea.

Euspongia.—The genus *Euspongia*, to which belong all the finer bath sponges, is a typical example of the true "horny" sponges or *Euceratosa*, characterized especially by the fact that the skeleton is not composed of spicules but of so called horny fibres. A living bath sponge appears as a dark-coloured, irregular or sometimes cup-shaped mass attached by the under surface to the sea-bottom. The outer surface is covered by a skin or dermal membrane, elevated in innumerable minute conuli by the growing apices of the primary

skeleton fibres. This skin is pierced by a vast number of inhalant dermal pores of microscopic size, and by a much smaller number of comparatively large vents or oscula. When the sponge is removed from the water the soft tissues rapidly decay and leave behind only the elastic "horny" skeleton, which is what we usually

apices at the surface of the sponge, and the presence of which may greatly injure the quality of the sponge. The connecting fibres are only about 0·035 mm. in diameter, or even less, and the primaries are a little thicker, while the meshes between the fibres are so narrow as to permit of the soaking up of water by capillary attraction,

the property upon which the economic value of the bath sponge depends. In the living sponge the fibres are embedded in the mesogloea, where they are secreted by special cells known as spongoblasts, which are often found thickly clustering around them (fig. 7). The canal-system (figs. 6, 8) is very complex and shows but little indication of its origin from a folded rhagon. The inhalant pores lead each into a short, narrow, inhalant canal; these unite in roomy subdermal cavities lying in the ectosome, and from these in turn the main inhalant canals come off. The latter divide and subdivide, and thus ramify through the deeper parts of the sponge amongst the flagellated chambers, to each of which a small number of slender canaliculi are ultimately given off (fig. 9). The chambers themselves, lined by the usual collared cells, are small and approximately spherical, and each one discharges its water through a short and narrow exhalant canaliculus (fig. 9). The openings of the inhalant canaliculi into the chambers, of which there are several, correspond to the prosopyles of an Olynthus, while the single exhalant opening, or apopyle, may possibly correspond to an Olynthus osculum. The exhalant canaliculi unite together to form larger and larger canals which finally lead the stream of water to the vents on the surface of the sponge (fig. 8). The various parts of the canal-system, other than the chambers themselves, are lined by a flat pavement-epithelium, and the mesogloea, occupying all the spaces between the different parts of the canal-system, contains cells of various kinds, embedded in a very granular matrix.

FIG. 9.—*Euspongia officinalis* (bath sponge). Part of a section such as is shown in fig. 6, more highly magnified, showing three flagellated chambers, with inhalant canaliculi on the left and exhalant canaliculi on the right.

Comparative Anatomy.

External Characters.—Amongst the simpler calcareous sponges, which are all of comparatively small size, the external form is usually symmetrical and is evidently a kind of outward expression of the arrangement of the canal-system. This is well seen in the simplest form of all, the sac-shaped Olynthus, and also in its simpler Syconoid and Leuconoid derivatives (described later on), which may be regarded either as individuals of a higher order or as colonies of Olynthus persons grouped around a central individual whose large gastral cavity opens to the exterior through the single osculum. In the more complex Leuconoids, however, the process of colony formation becomes very irregular and may give rise to great compound masses, with many vents. In these masses we may perhaps recognize the presence of individuals of three orders: (1) the primitive Olynthus persons, represented by the individual flagellated chambers; (2) the Leuconoid persons, indicated each by its osculum; and (3) the entire colony formed by the union of many such Leuconoid persons in an irregular manner. It is, however, very doubtful how far the flagellated chambers in such forms as this can be regarded as morphologically equivalent to Olynthus persons.

In the non-calcareous sponges we are always dealing with individuals of a high order, which usually form complex aggregates (colonies) of large size and very various shape. As a general rule the form of those non-calcareous sponges which grow in shallow water is extremely irregular and variable while at great ocean depths the shape is usually definite, constant and often exquisitely symmetrical, a fact which may perhaps be accounted for in part by the absence of disturbing influences such as are met with in shallow water. Perhaps the most extraordinary external form yet discovered is that of *Esperiopsis challengeri*, discovered by the "Challenger" expedition in deep water off the Philippine Islands (fig. 10), a form which reminds one strikingly of a number of flowers arranged in a raceme, except that the largest and oldest member of the compound colony is at the top of the stalk and the smallest at the bottom. In other deep-water species the external form may frequently be explained as an adaptation to the special exigencies of the environment. Thus, for example, many species are provided with long stalks which lift up the body of the sponge out of the soft ooze in which it would otherwise be smothered, while the bottom of the stalk is frequently extended in root-like processes which serve to attach it to some solid object (*e.g. Stylocordyla*). In other cases the sponge supports itself on the surface of the ooze by long stiff processes, formed of bundles of spicules which radiate from the central, cap-shaped body; this is known as the "Crinorhiza form," and is met with in several distinct genera (fig. 11). Amongst the Hexactinellida, which are essentially a deep-water group, many very beautiful external forms are met with, the best known, perhaps, being the so-called Venus's flower basket (*Euplectella*, fig. 12).

FIG. 11.—*Cladorhiza longipinna*: a deep-water Monaxonellid Sponge, showing the "Crinorhiza" form, adapted for support on soft ooze.

Flabellate (or fan-shaped) and cup-shaped forms are frequently met with even amongst shallow-water sponges, and in widely separated genera, such as *Poterion* (the great Neptune's cup sponge) and *Reniera testudinaria*. In *Phyllospongia* the flabellate and cup-shaped forms pass insensibly into one another, the cup being apparently merely a folded lamella. Slender branching forms are also not uncommon in shallow water, as seen in the common *Chalina oculata* of the British coast. Spherical forms, such as *Tethya*, likewise occur. By far the greater number of shallow-water sponges, however, are quite irregular in shape and either form crusts of varying thickness on the surface of rocks and sea-weed, or large and massive aggregates which may rise to a considerable height above the substratum. In the boring sponges (Family Clionidae) the sponge occupies an elaborate system of chambers and passages which it excavates for itself in the shells of Mollusca and other calcareous organisms. The common British *Cliona celata* begins

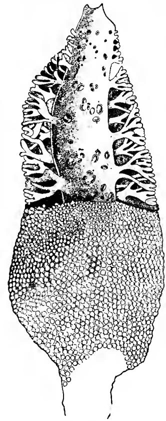
life in this way, but soon outgrows the housing capacity of its host, whose shell then serves merely as a base of attachment for the large independent sponge-colony.

One of the most striking features of living sponges is their colour, which is often very brilliant. Yellow, red, orange, purple, brown, black, green and blue are all met with, in varying degrees of purity and intensity, amongst the commoner Non-calcarea; whilst the calcareous sponges are usually white. It appears probable that the colour is more or less constant for each species, and may therefore afford a useful guide to specific identification. As a rule the colour is lost in spirit-preserved or dry specimens, but a noteworthy exception is found in the brilliant purple *Suberites wilsoni* of Port Phillip, in which the colour, though soluble in water, is permanent in dry specimens and in alcohol. The colouring matter is sometimes lodged in special pigment cells belonging to the sponge itself, and sometimes in symbiotic algae, with which the mesogloea is frequently filled.

Canal-system.—Whether we start with the primitive Olynthus form of the Calcarea or with the more advanced Rhagon of many Non-calcarea, it is evident that further advance in the complication of the canal-system is arrived at either by budding or folding, or by a combination of these processes. As, however, the canal-systems of the calcareous and of the main types of non-calcareous sponges have been evolved along perfectly independent lines it will be well to consider them separately.

In the genus *Leucosolenia* (Calcarea Homocoela) the primitive Olynthus form may, as we have already seen, give rise, by branching and anastomosing, to complex reticulate colonies of the Clathrina type, in which a pseudoderm, pierced by inhalant pores, may cover over a system of inhalant canals which are simply the interspaces between the branching tubes of which the colony is made up, while at the same time a centrally placed pseudogaster, which is simply a space enclosed by upgrowth of the colony around it, may form the main exhalant canal and open to the exterior through a well-defined vent or pseudosculum. In this direction perhaps the most remarkable modification arrived at is that of *Leucosolenia cavata*, in which the Clathrina tubes, lined by collared cells, widen out into large irregular spaces, while the inhalant interspaces become constricted into narrow canals lined by collared cells on the *outside*. We have here a kind of inversion of the ordinary Clathrina canal-system, but a perfectly gradual transition from the ordinary to the inverted condition is seen as we pass from the older to the younger parts of the colony.



(After Dendy. Simplified from a coloured plate in *Trans. Roy. Soc. of Victoria*, Melbourne, vol. iii. pt. 1.)

FIG. 13.—*Leucosolenia tripodifera*, with part of the sponge-wall cut away to show the arrangement of the radial outgrowths.

In *Leucosolenia* (*Dendya*) *tripodifera* (fig. 13) we find a totally different type of colony formation, which is of great importance as indicating in its canal-system the possible starting-point of a line of evolution which culminates in the highest Calcarea. Here a large central individual, whose spacious gastral cavity is lined by collared cells, gives off radial buds from all sides, which branch slightly and terminate in blind ends in contact with one another, so that the entire colony has an approximately even surface. The inhalant canals are represented by the interspaces between the radial tubes, between the blind extremities of which the water finds its way in from the outside. There is only a single vent, situate at the extremity of the central cavity. This cavity must be regarded as the original gastral cavity of a parent Olynthus, from which the radial tubes have been produced by budding.

We have next, amongst the Calcarea Heterocoela, the Sycon type of canal-system which differs from the foregoing in that the collared cells of the central gastral cavity are replaced by pavement-epithelium. The radial tubes now form definite flagellated chambers, pierced as before by numerous prosopyles through which the water enters from the spaces between the chambers, while the original gastral cavity forms a central exhalant canal terminating in the single vent, a true osculum, corresponding to the osculum of an Olynthus. In the simplest Syconoid forms (*Sycetta*) the radial chambers remain perfectly straight and unbranched. They do not touch one another at all and there is no trace of an ectosome or dermal cortex, and hence there are no true inhalant canals, and the water circulates without interruption between the chambers. In the genus *Sycon* (fig. 14) the walls of adjacent chambers come into contact with one another and fuse together and thus give rise to more or less well-defined inhalant "inter-canals." The chambers themselves may branch, and in some species of *Sycon* a thin, pore-bearing dermal membrane connects together their distal extremities and covers over the entrances to the inhalant canals. The canal-system now exhibits all the different parts found in the most highly-organized sponges: viz. dermal pores, inhalant canals, flagellated chambers, exhalant canal and osculum. In the genus *Grantia* and its allies (*e.g. Ute*, fig. 15) the thin dermal membrane of *Sycon* is converted into a well-developed cortex, covering the extremities of both the inhalant canals and the radial chambers, and sometimes containing a system of special cortical inhalant canals. We may now distinguish between an ectosome (the dermal cortex), which contains no flagellate chambers, and a choanosome in which chambers are present. The next stage has probably been arrived at by a kind of folding of the choanosome, for we find the chambers arranged

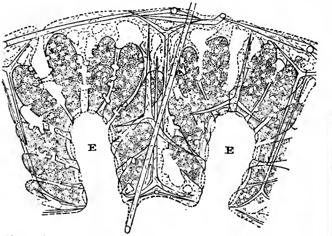
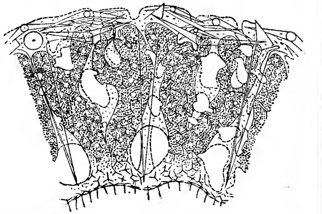
radially, not around the central gastral cavity but around diverticula of the latter which form special exhalant canals. This condition, sometimes called the "sylleibid" type, is not characteristic of any particular genus or family, but occurs in a few isolated species, such as *Leucilla connexiva* (fig. 16). A somewhat similar condition may be arrived at by branching of the radial flagellated chambers, as in *Heteropegma* (fig. 17). The next stage is marked by great reduction in the size of the chambers, which may become almost spherical, and by further folding of the choanosome, so that in a section of the sponge-wall we see the small chambers scattered irregularly in the mesogloea between the numerous branches of complicated inhalant and exhalant canals. Each chamber still has several prosopyles, through which it receives water from the ultimate branches of the inhalant canals, while it opens into a relatively large exhalant canal by a wide apopyle. This is the highest type of canal-system met with amongst the Calcarea. It is sometimes known as the Leucon type and is seen in most species of the genus *Leucandra*, as well as in many others.



(After Poléjaeff.)

Fig. 16.—*Leucilla connexiva*, part of transverse section, showing "sylleibid" type of canal system with folded chamber layer and exhalant canals (E) into which the chambers open.

It is almost identical with one of the types commonly found in non-calcareous sponges (e.g. *Plakina*, fig. 4), but has of course been evolved independently. The various types of canal-system met with in the Calcarea are connected together by numerous intermediate forms, thus forming a very interesting evolutionary series, while both the Sylleibid and Leuconoid types appear to have been independently evolved several times, thus affording excellent examples of the phenomenon of convergence, a phenomenon which is very frequently met with amongst sponges.

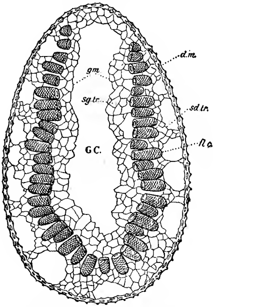


(After Poléjaeff.)

Fig. 17.—*Heteropegma nodus-gordii*, part of transverse section, showing branching flagellated chambers and huge subdermal quadriradiate spicules, with greatly reduced tubar skeleton.

In describing the anatomy of *Plakina* as a type of non-calcareous sponge, we have traced the development of a fairly complex canal-system from the so-called Rhagon form. We can, however, hardly regard the Rhagon as representing a fundamental type of canal-system common to all the Non-calcarea, for in some of the Myxospongida, which are the most primitive of all, and again in the Hexactinellida, we find a type characterized by the presence of elongated sac-shaped flagellated chambers resembling those of the Sycon type amongst the Calcarea, and these chambers are arranged radially around the exhalant canals (*Halisarca*, Hexactinellida). The first recognizable stage in the evolution of the canal-system of the Non-calcarea would thus appear to be a condition not unlike that of *Sycon*, with a number of elongated chambers arranged radially around a central gastral cavity and having their blind outer extremities covered over by a dermal membrane. This stage is very nearly reproduced in the young form of a Hexactinellid sponge, *Lanuginella pupa*. From some such form the Rhagon type may perhaps be derived by flattening out of the lower end of the sponge into a broad base of attachment, and by reduction in the size of the flagellated chambers, accompanied by a more irregular arrangement.

Starting from the primitive Myxosponge ancestor, with large sac-shaped chambers, radially arranged, the Non-calcarea have apparently developed along four main lines, giving rise to the existing Myxospongida, the Hexactinellida (Triaxonida), the Tetraxonida



(After F. E. Schulze. From Lankester's *Treatise on Zoology*.)

and the Euceratosa. The Myxospongida have retained the large size of the chambers in certain forms (*Halisarca, Bajalus*), but have lost this primitive character in the more advanced members of the group (*Oscarella*). The Hexactinellida have retained the large size and radial arrangement of the flagellated chambers throughout their entire series. The chamber layer, however, tends to become more or less folded (fig. 19), and always lies between two layers of

loose trabecular tissue in which the canals are represented by irregular spaces. The Tetraxonida appear to have suffered reduction in the size of the flagellated chambers at a very early date, and it is of this group especially that the Rhagon type is characteristic (e.g. *Plakina*, fig. 4). The Euceratosa exhibit a beautiful series, beginning with forms (*Aplysillidae*) having large sac-shaped chambers like those of Hexactinellids and ending with forms (*Spongiidae*, *Euspongia*, figs. 6, 8, 9) having small spherical chambers.

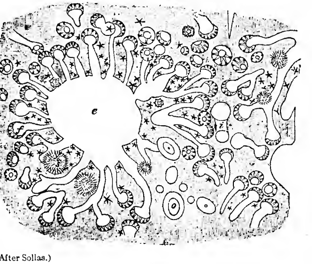
Along all four lines of descent it is probable that folding of the choanosome, or chamber-bearing layer of the sponge-wall, has played a very important part in the evolution of the canal-system. This folding is very clearly seen in the Hexactinellida and in such forms as *Oscarella* (Myxospongida) and *Plakina* (Tetraxonida). By this process inhalant and exhalant canal-systems have been formed, and then the ends of the inhalant canals have in most cases been closed in by development of an ectosome, as in *Plakina trilopha* and *Stelletta phrissens* (fig. 20). In the majority of cases (e.g.

(After Sollas.)

FIG. 20.—Young specimen of *Stelletta phrissens* (Sollas). Vertical section through the osculum (*o*), showing the choanosome folded within the ectosome.

Euspongia) the folding has become so complex that it is no longer recognizable as such, and the origin of the now well-defined inhalant and exhalant canals is completely disguised. In many cases the principal exhalant canals may be surrounded by a layer of tissue of considerable thickness in which there are no flagellated chambers at all, known as the endosome, so that the folded choanosome may be sandwiched in between ectosome on the outside and endosome on the inside.

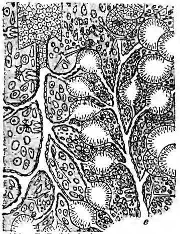
The manner in which the flagellated chambers communicate with their respective branches of the inhalant and exhalant canal-



(After Sollas.)

FIG. 21.—Transverse section across an exhalant canal and surrounding choanosome of *Cydonium eosaster* (Sollas), showing the aphodal flagellated chambers.

system varies considerably in different forms, and the following types are recognizable, though by no means sharply distinguished from one another. In the more primitive forms (e.g. Hexactinellida, Aplysillidae, Spongeliidae) each chamber is provided with several prosopyles and receives its water supply direct from relatively large inhalant canals or even lacunae, discharging it again through a wide mouth (apopyle) into a relatively large exhalant canal or lacuna which also receives water directly from other chambers. To this type (fig. 4, *f*) the name "eurypylous" has been given, and we may include in it cases where there is only a single prosopyle, and perhaps even a short, narrow inhalant canal. In more advanced forms the water is discharged from each chamber through a narrow exhalant canaliculus (aphodus) peculiar to itself, and thence into wider canals. This is known as the "aphodal" type (e.g. *Cydonium*, fig. 21). In the "diplodal" type there is a special inhalant canaliculus (prosodus) as well as a special aphodus to each chamber, with usually, at any rate, only a single prosopyle (e.g. *Corticium*, fig. 22). The progress from the eurypylous to the diplodal condition is accompanied by a corresponding increase in the development of the mesogloea, whereby the canals are greatly restricted in diameter, and at the same time the mesogloea tends to lose its transparent gelatinous character and to become compact and granular.

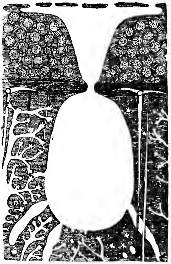


(After F. E. Schulze.)

FIG. 22.—Part of a section of *Corticium candelabrum*, O.S., showing diplodal type of canal-system. The canal shown on the left is inhalant and that on the right (*e*) exhalant.

With the growth of the ectosome we necessarily get a corresponding development of the proximal portion of the inhalant canal-system. At first the ectosome is merely a thin membrane, the *dermal membrane*, pierced by the inhalant pores, which are usually arranged in groups. Beneath the groups of pores (pore-areas) lie spacious *subdermal cavities* which form the commencement of the inhalant canal-system in the choanosome. In more advanced types the ectosome becomes greatly thickened and may be specially strengthened in a variety of ways to form a *cortex*. The inhalant pores now no longer lead directly into the subdermal cavities, but first into a series of cavities lying in the cortex and known as *chones*, which may be separated from the underlying subdermal cavities (sub-cortical crypts) by definite sphincters (*Cydonium*, fig. 23).

The arrangement of the oscula and pores on the surface of the sponge varies greatly in different types, and sometimes gives rise to very striking modifications of the external form. The oscula or vents are usually relatively large openings situated on the more prominent parts of the sponge, often on special elevations. Occasionally they are replaced by sieve-like oscular areas (e.g. *Geodia perarmata*), a modification which doubtless serves to prevent foreign bodies from entering the wide exhalant canals. The inhalant pores may be irregularly scattered over the surface of the sponge or collected in more or less well-defined pore-areas. In cup-shaped sponges the pores are usually confined to the outer and the oscula to the inner surface. In flabellate sponges we find pores on one side and oscula on the other. In *Tedania actiniiformis*, a deep-sea form, the pores are restricted to a narrow band surrounding the columnar body of the sponge just beneath the flattened top, which bears the vents; thus they are kept from being choked up by the soft ooze on which the sponge lies. In *Xenospongia*, a flattened discoid form, they are confined to narrow grooves on the upper surface, the chief of which run round the margin of the disk. In *Esperella murrayi* the pores are also confined to special grooves on the surface of the sponge, and in both these cases the grooves can apparently be opened and closed by special bands of muscle-fibres, and the supply of water thus regulated. In some species of *Latrunculia* we find the surface of the sponge covered with



(After Sollas.)

FIG. 23.—Section through the cortex and part of the choanosome of *Cydonium eosaster* (Sollas), showing a pore-sieve and underlying chone in the cortex. conspicuous projections of two kinds, some conical and bearing each a single vent, others truncated at the top and bearing the inhalant pores.

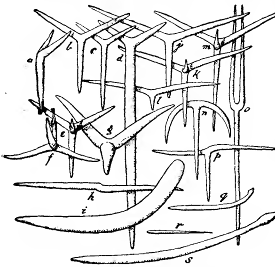
Skeleton.—The original ancestral form (*Protolynthus*) from which all the Porifera are supposed to be descended, probably possessed no proper skeleton at all, and this condition has been retained in the existing Myxospongida, although these sponges have made considerable progress in the evolution of their canal-system. There appears to be little doubt that the Myxospongida are *primitively* devoid of skeleton, and in this respect they must be carefully distinguished from the genus *Chondrosia*, in which the skeleton has been secondarily suppressed, as well as from numerous and divers species in which the proper skeleton has been more or less completely replaced by grains of sand or other foreign bodies. The Calcarea, Triaxonida, Tetraxonida and Euceratosa, except in cases of extreme degeneration, all possess a well-developed proper skeleton. As this skeleton has been independently evolved in each of these great groups it is necessary to deal with it separately in each case.

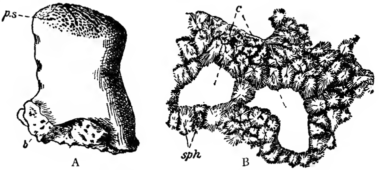
Calcarea.—The skeleton in this group is composed of spicules of crystalline carbonate of lime (usually calcite), developed within special mother-cells or scleroblasts. Each spicule is enclosed in a delicate membranous spicule-sheath and contains an axial thread of organic matter. Three main types of calcareous spicule are met with, triradiate, quadriradiate and monaxon (fig. 24). The triradiates and quadriradiates, however, are not simple spicules, but spicule-systems formed of three or four rays each originating independently from its own scleroblast (actinoblast) and all uniting together secondarily. There is reason to believe that this may also sometimes be the case with the monaxon or oxeate spicules. In the most primitive triradiate spicules all three rays lie in the same plane. Three chief varieties may be distinguished: (1) Regular (fig. 24, *b*), with all the rays and all the angles equal; (2) Sagittal (fig. 24, *c*, *d*, *l*, &c.), with two of the rays or two of the angles forming a pair, differentiated in some respect from the remaining ray or angle, the paired rays being termed "oral" and the odd ray "basal"; (3) Irregular (fig. 24, *p*), when conforming to neither of the above types. It has been proposed to draw a very sharp distinction between "equi-angular" triradiates and "alate" forms (in which the angle between the oral rays differs from the paired angles), but it may be doubted whether such a distinction has any great value. The quadriradiate (fig. 24, *e*, *f*, *k*, *m*) is formed by the addition of an "apical" or "gastral" ray to the three "facial" rays of the triradiate; this ray lies in a plane at right angles to that of the facial rays. The monaxon spicules (fig. 24, *h*, *i*, *q*, *r*, *s*) are straight or curved and the two ends are usually more or less sharply differentiated from one another. In all these spicules the form and arrangement of the rays is usually clearly correlated with their position in the sponge in such a manner that they are specially adapted for the work which they have to do.



(After E. A. Minchin. From Lankester's *Treatise on Zoology*.)

FIG. 24.—Spicules of Calcareous Sponges.

The arrangement of the spicules in the case of the genus *Leucosolenia* has been dealt with above, and we must pass on at once to the Calcarea Heterocoela. In this group the skeleton exhibits an evolutionary series no less remarkable than that of the canal-system. We may take as a convenient starting-point the genus *Sycetta*, a typical Syconoid form, with the flagellated chambers radiating independently from the central gastral cavity. The wall of the gastral cavity is supported by a gastral skeleton of triradiate or quadriradiate spicules. These may be sagittal, in which case the oral rays are turned towards the osculum while the basal ray is directed downwards. If there is an apical ray it projects into the gastral cavity. The walls of the radial chambers are supported by a special "tubar" skeleton (cf. fig. 14), consisting exclusively of triradiates with their basal rays directed towards the distal end of each chamber. The oral rays are spread out at right angles to the length of the chamber, and as several spicules generally lie at the same level the tubar skeleton forms a series of more or less definite joints and is said to be "articulate." This type of skeleton is almost invariably associated with the Syconoid type of canal-system. In the genus *Sycon* itself we find the distal ends of the chambers specially protected by tufts of monaxon spicules (fig. 14), but the next great advance in the evolution of the skeleton is brought about by the development of a dermal cortex, in which a special dermal skeleton is developed. This is well seen in the genus *Ute* (fig. 15). After this the skeleton of the chamber layer in the sponge-wall begins to undergo modifications, some of which are obviously correlated with the gradual change of the canal-system from the Syconoid to the Leuconoid condition (cf. figs. 16 and 17). Finally all trace of the articulate tubar skeleton is lost, and we get a "parenchymal" skeleton of scattered radiate spicules in the chamber layer. The skeleton of the chamber layer, no matter what the type of canal-system, may be supplemented by large subdermal sagittal triradiates or subdermal quadriradiates (fig. 17), whose basal or apical rays project inwards from the dermal cortex (Heteropidae and Amphoriscidae). Very generally a special "oscular" skeleton is developed in the form of a fringe of long monaxon spicules around the vent.



(After J. J. Lister.)

A, Entire sponge (x 3): *p.s.*, upper surface with openings of canal-system; *b*, base of attachment.

B, Section of skeleton: *sph*, spherules of arragonite; *c*, canals.

Various aberrant types of skeleton are met with in the group. In the genus *Lelapia* we find a partly fibrous skeleton, in which the fibres are composed of bundles of triradiates shaped like tuning-forks (fig. 24, *o*), and in *Petrostoma* the main skeleton is formed of calcareous spicules actually fused together. In *Astrosclera* (fig. 25) a very anomalous type of calcareous skeleton is found, consisting of spherical masses of arragonite, each originating in a special scleroblast and having a radiate structure, recalling that of a siliceous

sterraster. These bodies become closely packed together over large areas, and give the sponge a stony hardness.

Hexactinellida.—In this group the skeleton is composed of spicules of colloidal silica deposited in concentric lamellae around slender axes of an organic substance which in life occupies the "axial canal" of the spicule. Although varying greatly in detail and often exhibiting great complication or, it may be, reduction in structure, these spicules are all referable to the same fundamental triaxonid and hexactinellid type, characterized by the possession of three axes intersecting each other at right angles and each thereby divided into two rays or actines (fig. 26, *e*). According as one, two, three, four or five of these actines are suppressed we distinguish between pentact, tetract, triact, diact and monact spicules, and these may be further subdivided according to special modifications of the rays due to secondary branching, ornamentation by spines,

knobs, &c., or curvature, or to excessive development of certain rays as compared with the remainder. Some of the most characteristic of these special types are represented in figs. 27 and 28. Two of them require special notice on account of their importance in the classification of the group. These are the *hexaster* and the

(After F. E. Schulze.)

FIG. 28.—Derivatives of the Hexact type of Spicule, found in Hexactinellida.
a, Uncinaria; *b*, Clavula; *c*, Scopula.

amphidisc. A hexaster (=rosette) is a perfectly symmetrical hexact whose actines branch out into secondary or terminal rays, in a star-like manner (fig. 30, *t*). Various sub-types are distinguished according to the character of the rays (*floricome*, *plumicome*, &c.). An amphidisc (fig. 27, *d*) is a diact spicule consisting of two opposite rays each of which terminates in a disk-like or spherical expansion surrounded by marginal teeth.

In some cases the spicules all remain disconnected from one another (Lyssacine condition), in others some of them may be united by siliceous cement into a continuous framework (Dictyonine condition), and the distinction between these two types of arrangement was for a long time regarded as indicating a primary subdivision of the Hexactinellida into Lyssacina and Dictyonina, but this subdivision has now been abandoned. The term *prostalia* is applied to spicules which project freely from the surface of the sponge, and these are further distinguished as *basalia*, *pleuralia* and *marginalia*, according to their position at the base of the sponge, on the sides, or round the margin of the osculum. The basalia frequently form a root-tuft for attaching the sponge to the substratum (*Hyalonema*, *Euplectella*) and commonly have anchor-like distal extremities. They may be extremely long, as in the well-known "glass-rope" of *Hyalonema*. In the remarkable genus *Monorhaphis* we find a single gigantic diact spicule, which may attain a length of two or three feet and the thickness of a lead pencil, transfixing the body of the sponge like a skewer from above downwards. A special dermal skeleton is usually formed by a number of spicules distinguished as *dermalia*, and a gastral skeleton may be similarly formed by special *gastralia* surrounding the central gastral cavity. Between the dermal and gastral skeletons another set of spicules, known as *parenchymalia*, form the most important part of the skeleton, supporting the chamber-layer and adjacent tissues. The distinction into large *megascleres* and small *microscleres* is perhaps less well marked in this group than in the Tetraxonida.

Tetraxonida.—Here, again, the spicules are composed of colloidal silica deposited around organic axial threads. The starting-point in the evolution of the very complex series of tetraxonid spicules is the primitive tetract or calthrops, characteristic of the most primitive members of the group (e.g. *Plakina*). This fundamental ground-form (fig. 26, *d*) consists of four rays or actines of equal length, which all meet one another at equal angles in the centre of the spicule, while their apices would occupy the four angles of a regular pyramid whose sides are four equilateral triangles. It is thus both *tetraxonid* (with four axes) and *tetractinellid* (with four rays). In *Plakina* the spicules are all of about the same size, neither very large nor very small, but in higher forms we usually find some of the spicules enlarged to form megascleres and others reduced to form microscleres. The megascleres play the principal part in building up the skeleton while the microscleres are usually scattered through the mesogloea.

Triaene Series of Megascleres.—When three rays (cladi) of the tetract resemble one another, while the fourth (shaft) differs in some respect the spicule is termed a *triaene*. The simplest form is the *plagiotriaene* (fig. 29, 2), with three short simple cladi and an elon-

gated shaft, the angles all remaining approximately equal. If the angles between the cladi and shaft become approximately right angles we have an *orthotriaene*. If the cladi point forward, we have a *protriaene* (fig. 29, 6). If the cladi are turned backwards towards the shaft we have an *anatriaene* (fig. 29, 5). If the cladi branch each into two we have a *dichotriaene* (fig. 29, 3). If the cladi are expanded laterally and fused together to form a plate, while the shaft is reduced, we have a *discotriaene* (fig. 29, 4). The cladi may be reduced in size or even suppressed (fig. 29, 7, 8), leaving only the shaft, which may be either sharp at each end (*oxeate*) or sharp at the apex and rounded at the base (*stylote*). The spicule has now become monaxonid or monaxonellid (*i.e.* with a single axis) and monactinellid (with only a single ray); but this condition may also be arrived at in a different way, as we shall see directly.

The *tetracrepid desma* (fig. 29, 9), characteristic of many Lithistids, has been derived from the primitive tetract by ramification of the ends of all the rays.

Monaxonid Series of Megascleres.—We have already seen, in *Plakina*, how a diactinellid spicule may arise by suppression of two rays of the tetract (fig. 5). At first the two remaining axes are distinctly indicated by the presence of an angle in the middle of the spicule (fig. 29, 10); by straightening out of this angle we reach a monaxonid but diactinellid condition—the diactinellid oxeate, with the organic centre of the spicule in the middle (fig. 29, 11). By rounding off of both ends this form passes into the *strongylote* (fig. 29, 17), then if both ends become enlarged into knobs it is said to be *tylote* (fig. 29, 18). If one end only is rounded off, which apparently usually takes place by suppression of one ray, while the other remains sharp, the spicule is termed *stylote* (fig. 29, 12). It is now monactinellid as well as monaxonid. If the blunt end of the style enlarges to form a knob we have the *tylostyle* (fig. 29, 13). *Acanthoxeates* (fig. 29, 16), *acanthostyles* and *acanthotylostyles* (fig. 29, 14) are formed by the development of spines on the surface of the spicule. The development of large recurved spines at the apex of a tylostyle gives us the *cladotylote* or grapnel spicule (fig. 29, 15), which simulates an anatriaene. By enlargement of the spiny base of an acanthotylostyle and suppression of the shaft we get forms which simulate astrose microscleres and may be called *pseudasters* (fig. 29, 14*a*, 14*b*). Pseudasters may also be developed by shortening up of acanthoxeates, accompanied by enlargement of the spines (e.g. *Spongillinae*, fig. 29, 16*a*). The *exotyle* appears to have been formed by enlargement of the outer end of a radially placed oxeate at the surface of the sponge. By ramification of both ends of a diactinal megasclere we get the *monocrepid desma* (fig. 29, 20), characteristic of certain Lithistids and closely simulating the tetracrepid desma. By ramification of one end of a strongylote spicule we may get a *cladostrongyle* (fig. 29, 19).

Diactinal Series of Microscleres.—The starting-point of this series is the primitive angulate, diactinal oxeate (fig. 29, 10). This has given rise to long hair-like forms or *rhaphides* (fig. 29, 28), short hair-like forms associated in bundles and called *trichodragmata* (fig. 29, 29), bow-shaped forms or *toxa* (fig. 29, 34), and C- and S-shaped forms or *sigmata* (fig. 29, 30). From the sigmata may be derived the *diancistra* (fig. 29, 33), shaped like pocket-knives with a blade half open at each end, and the wonderful series of *chelae* (fig. 29, 31, 32), in which each end branches into a number of sharply recurved teeth. These chelae are characteristic of the family *Desmacidonidae*, and exhibit great variations in detail, while each particular form is remarkably constant in the species in which it occurs. The most curious and aberrant are those of *Melonanchora* (fig. 30, *l*) and *Guitarra*. In *isochelae* the two ends of the spicule are equal, in *anisochelae* they are unequal.

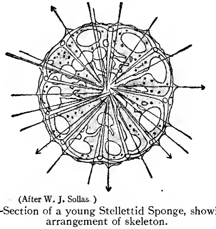
Astrose or Polyactinal Series of Microscleres.—For the beginning of this series we must go back to the primitive tetract. Reduction in size, sometimes accompanied by increase in the number of rays, has given rise to the *oxyaster* (fig. 29, 26), with sharp rays and no conspicuous centrum. The development of a distinct centrum from which numerous rays come off gives us the *spheraster* (fig. 29, 22). In the *sterraster* (fig. 26, *g*, *h*), characteristic of the family *Geodiidae*, numerous slender rays become fused together side by side to form a solid ball. In the *spiraster* (fig. 29, 24) the centrum appears to have become elongated and twisted into a spiral. The rays of the aster may terminate in knobs as in the *chiaster* (fig. 29, 25), or they may become branched (fig. 29, 27).

Arrangement of the Skeleton in the Tetraxonida.—The most primitive type of skeleton arrangement in this group was probably very similar to that which we still find in *Plakina* or *Dercitopsis*, but without any special dermal spicules, the skeleton consisting exclusively of small isolated tetracts irregularly scattered through the mesogloea between the chambers. We may call this the scattered or diffuse type of skeleton. With the development of an ectosome —whether thin dermal membrane or thick cortex—a special dermal skeleton arose. Sometimes this consists of small specially differentiated dermal spicules—candelabra in *Plakina*, oxeates in *Dercitopsis*—but a much more important series of modifications was



(After W. J. Sollas.)

FIG. 31.—Section of a young Stellettid Sponge, showing radial arrangement of skeleton.

initiated by the development of the triaenes. The cladi of these spicules are commonly extended in or beneath the ectosome and form a very efficient dermal skeleton, while the shafts are directed centripetally through the choanosome. In the genus *Discodermia* the discotriaenes form a continuous dermal armour of siliceous plates. When anatriaenes and protriaenes are developed their cladi commonly project beyond the surface of the sponge and render it more or less strongly hispid, thus forming a protection from the attacks of enemies. The shafts of the triaenes, though greatly reduced in *Discodermia*, usually become very much hypertrophied and may be grouped together in bundles, often associated with oxeate spicules. These spicules, or bundles of spicules, now form the principal part of the skeleton, and inasmuch as they radiate from the interior towards the surface of the sponge we distinguish this as the radiate type of skeleton. The skeleton of the vast majority of Tetraxonida is either actually radiate in structure or derived from the radiate type by further modification. In many Stellettidae, for example (fig. 31), we have a typical radiate skeleton in which a large number of the spicules retain the primitive tetractinellid form, though associated with oxeates, while in *Tethya* the skeleton is arranged in a similar manner but only monaxonid spicules are present. From the radiate we pass to the reticulate type of

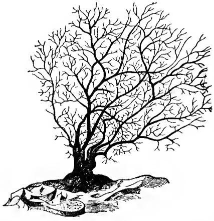
skeleton which characterizes the majority of the so-called Monaxonellida. This is derived from the former by the establishment of secondary spicule-bundles connecting the primary or radial bundles together, and the transition is usually accompanied by loss of the cladi of the triaenes and by the development of a massive irregular form on the part of the entire sponge. An intermediate condition is found in some of the massive species of *Tetilla* (*e.g. T. limicola*), in which the spicule-bundles are very well defined and form distinct primary "fibres" in the interior of the sponge, but no distinct secondary or connecting fibres are yet developed.



(After Lendenfeld. Modified from Lendenfeld's *Horny Sponges*, by permission of the Royal Society of London.)

FIG. 33.—Dendritic, Euceratose Skeleton of *Dendrilla rosea*.

In the Sigmatomonaxonellida, derived from the Tetillidae, the reticulate type of skeleton is almost universal, and in this group an entirely new element is introduced into the skeleton with the development of a "horny" cementing material (spongin) which unites the spicules together in the fibres. At first small in quantity (*Reniera*, fig. 32, A), the spongin cement gradually increases in proportion to the spicules until in many Chalininae (fig. 32, B, C) and *Desmacidonidae* the spicules become completely embedded in it, and the fibres may be formed chiefly of spongin, with only a core of spicules. The complete enclosure of the spicules by spongin at a very early stage cuts off their food supply and causes arrest of development. Finally, in some Chalininae (fig. 32, D) and *Desmacidonidae* the spicules entirely disappear from the interior of the fibre, and if at the same time they happen to be absent from the intervening mesogloea we get a skeleton composed exclusively of horny matter or spongin, to which the term *pseudoceratose* may be applied. In the sub-family *Ectyoninae* the skeleton becomes modified in an interesting manner by the development of "echinating" spicules, usually acanthostyles or acanthotylostyles, whose bases are cemented on to the fibre by spongin while their apices project into the surrounding soft tissues. These doubtless serve as a defence against internal parasites. In *Agelas* these echinating spicules may persist after the spicules have entirely disappeared from the interior of the strongly developed horny fibre. In the Axinellidae all the spicules in the fibres are typically more or less echinating in character and the fibres become plume-like.

Very frequently a special dermal skeleton is developed in the ectosome altogether distinct from that formed by the cladi of the triaenes (when these are present). Thus in the Geodiidae (fig. 23) the thick cortex is almost filled with densely packed sterrasters. In many forms there is a dense layer of small radially arranged monaxons at the surface of the sponge, whose projecting apices form an efficient protection. In the reticulate forms the ectosome is usually a thin dermal membrane supported by a reticulate dermal skeleton of slightly different structure from the "main" skeleton. In cases where a special stalk or a root-tuft is developed we also find a special and appropriate skeleton in connexion therewith.

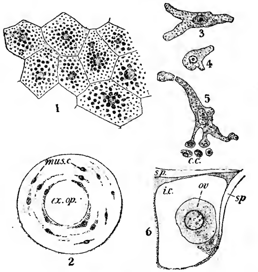
In the so-called Lithistida alone amongst the Tetraxonida do we find the spicules (desmas) united together by silica to form a coherent skeleton, sometimes of stony hardness, very different from the elastic, flexible skeleton resulting from the development of spongin, and analogous to the condition met with in the Dictyonine Hexactinellids.

The microscleres usually play quite a subordinate part in the formation of the skeleton, being scattered irregularly throughout the mesogloea, though sometimes (*Geodia*, *Tethya*) the asters may form a definite cortical layer.

Euceratosa.—In the true horny sponges, if we neglect for the moment the presence of foreign bodies, we may say that the skeleton consists from the first exclusively of spongin, secreted (by special spongoblasts) in concentric layers to form very well defined fibres. In the most primitive forms (Aplysillidae) this horny skeleton is dendritic in arrangement (fig 33), composed of fibres which rise vertically upwards from the base of the sponge (where they may be expanded to form a horny basal cuticle which serves for attachment) and ramify towards the surface, where their apices push against the dermal membrane and cause it to project in the form of "conuli." No reticulation is formed in the simplest cases (*Aplysilla*, *Dendrilla*), but in *Megalopastas* secondary connecting fibres are established (in relation, doubtless, to the increase in size and massive form of the sponge), and the skeleton thus simulates the pseudoceratose reticulate type of the Sigmatomonaxonellida. In *Darwinella* we have, in addition to the dendritic skeleton, isolated "spicules" of spongin scattered irregularly through the mesogloea. The presence of these spicules, which are sometimes, though by no means always, hexactinellid in form, has given rise to much speculation as to the possible relationship of the Aplysillidae to the siliceous Hexactinellida. Until we know more about their origin, however, we may perhaps best regard them simply as detached portions of the general skeleton secreted by isolated groups of spongoblasts. The genus *Megalopastas* forms a natural transition to the Spongeliidae, in which the reticulation of the horny skeleton is an almost constant feature, and in which the tendency to supplement or replace the spongin by foreign bodies (sand, broken spicules) is very strongly marked. In extreme cases the skeleton is composed almost exclusively of sand (*e.g. Psammopemma*), and the whole sponge looks like a mass of sand stuck together by a minimum of soft tissues and spongin cement. Such "arenaceous" sponges also occur in other groups (*e.g. Desmacidonidae*). The culminating point in the development of the true horny skeleton is found in the Spongiidae (*e.g. Euspongia*), but even in the bath sponge (fig. 6) we commonly find sand grains or other foreign matter in the interior of the primary fibres. The value of the sponge for domestic purposes depends upon the softness and elasticity of the fibre, the closeness of the meshes, and the relative absence of sand.

Histology.

There are two primary tissue-forms in sponges, the flat pavement epithelium and the epithelium composed of choanocytes or collared cells. The former covers the whole of the external surface of the sponge and, except in the simpler Calcarea Homocoela, it also lines a considerable portion of the canal-system. The latter lines practically the whole of the primitive gastral cavity in the Calcarea Homocoela, but in all higher types becomes restricted to well-defined "flagellated chambers." A gelatinous "mesogloea," which must be regarded primarily as an intercellular substance, appears between the primitive outer and inner layers of the sponge-wall. This contains primitive amoeboid wandering cells (archaeocytes),



(After Dendy. From *Quart. Journ. Micro. Science*, new series, vol xxxv., by permission of J. and A. Churchill.)

which give rise to the ova and spermatozoa, and also various other cells which are now generally believed to migrate into it from the primitive pavement epithelium (dermal epithelium) of the outer surface, such as scleroblasts, various connective tissue elements and contractile fibres.

Pavement Epithelium (fig. 34,1).—This always consists of a single layer of polygonal cells, which are usually flat and very rarely (*Oscarella*) provided with cilia or flagella. They may be glandular and may secrete a definite cuticle (as in many Euceratosa). They may also be highly contractile.

Porocytes.—In certain Calcareous sponges (*Leucosolenia*) it has been shown (by E. A. Minchin) that the primitive inhalant pores (prosopyles) are formed as perforations in certain of the pavement epithelium cells, which acquire a tubular form and extend through the mesogloea from the dermal to the gastral surface. The outer portion of each porocyte forms a contractile diaphragm which doubtless regulates the admission of water to the gastral cavity. The porocytes are sometimes conspicuous on account of their highly granular character.

Scleroblasts.—We may distinguish three kinds of scleroblasts, according to the chemical character of the skeletal material which they secrete; these are *calcoblasts*, *silicoblasts* and *spongoblasts*. The calcoblasts and silicoblasts (fig. 35, *h–n*) form their respective spicules, at any rate in the first instance, as intra-cellular (perhaps sometimes intra-syncytial) secretions, though we must suppose that in the case of large spicules the later stages in growth are accomplished by the activity of several or many scleroblasts in co-operation. The spongoblasts (fig. 7) appear to co-operate with one another in the formation of the spongin fibre from the beginning. They are found only around the young, growing fibres, where they occur in large numbers, forming a kind of sheath of somewhat flask-shaped cells, each placed at right angles to the surface of the fibre and with the nucleus in its broad distal end. The spongin is secreted in concentric lamellae and is obviously intercellular in origin, and probably of the same nature as the cuticle which often occurs on the surface of the sponge.

h–n, Silicoblasts or mother-cells, in which different forms of siliceous spicules are being secreted.

Connective-tissue Elements.—The following are the chief forms assumed by the mesogloea according to the nature of its connective-tissue cells and intercellular substance. (*a*) *Collenchyme*, consisting of a clear gelatinous matrix with branching stellate *collencytes* (fig. 35, *a*) embedded in it; (*b*) *Sarcenchyme*, in which the quantity of intercellular matrix is greatly reduced and the connective-tissue cells are closely packed together; (*c*) *Cystenchyme* (fig. 7, *Coll*, fig. 35, *c*), consisting of close-packed, oval, vesicular cells with fluid contents and strands of protoplasm radiating from the nucleus to the periphery; (*d*) *Chondrenchyme* (fig. 35, *b*), somewhat resembling cartilage in texture and with a very large amount of intercellular matrix.

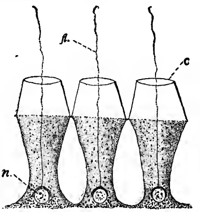
The name *desmacytes* has been given to certain slender connective-tissue fibres (fig. 35, *d*) often united in dense bundles or layers, which occur especially in the ectosome of many Tetraxonida, giving rise to a fibrous cortex of leathery consistence.

Contractile Fibres.—Muscular fibres or *myocytes* (fig. 35, *e*) are of common occurrence, especially in relation to various parts of the canal-system, the diameter of which appears to be regulated by their agency. They may form definite sphincters around the vents or in other places (fig. 34, 2), or they may form transverse bands lying in the floor of pore-bearing grooves, by the contraction of which the lips of the groove are doubtless approximated and the incurrent stream of water shut off (*Esperella murrayi*, *Xenospongia patelliformis*).

Endothelial Cells.—In many sponges the developing embryos are enclosed in definite capsules composed of flattened polygonal cells, the whole being embedded in the mesogloea. The origin of the endothelial cells forming the capsules is doubtful. They sometimes aid in the nutrition of the developing embryo (*e.g.* in *Stelospongus flabelliformis*).

No nervous elements, nor sensory cells of any kind, have as yet been recognized with any degree of certainty in sponges, in spite of various heroic attempts to demonstrate their existence.

Collared Cells or Choanocytes (fig. 35, *g*).—These are quite the most characteristic histological elements met with in sponges. Although exhibiting various minor differences in structure, and still more as regards size, they always show the same essential features. Each consists usually of an oval or rounded body (frequently appearing polygonal from the pressure of its fellows) surmounted by a more or less cylindrical or funnel-shaped collar, which surrounds a single long, whip-like flagellum projecting from the apex of the cell. The collar is a filmy, transparent extension of the cytoplasm (cell-protoplasm), which can be completely withdrawn. The flagellum may also be withdrawn, and in preserved specimens neither collar nor flagellum is usually visible. The cell is usually broadest at the base and narrowed to form a neck or "collum," beneath the collar. The nucleus may be situated either at the base or at the apex of the cell-body or between the two. The collar itself is often a more complicated structure than appears at first sight. It may be provided with one or two transverse hoops, presumably serving to stiffen it (*Ascandra falcata*). In many cases the collars of adjacent choanocytes have been observed to be connected by a definite membrane which stretches from one to the other at the level of their margins. This is known as *Sollas's membrane*, but it is apparently not a permanent structure, and the circumstances under which it appears require elucidation. In the Hexactinellida the form of the collared cells appears to be somewhat unusual (fig. 36).



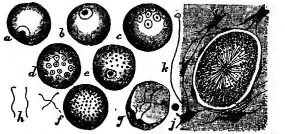
(After F. E. Schulze.)

FIG. 36.—Collared Cells of *Schaudinnia arctica*.

n, Nucleus; *fl*, Flagellum; *c*, Collar.

Archaeocytes.—The term "archaeocytes" has been applied to certain undifferentiated amoeboid cells which make their appearance at an extremely early stage in the ontogeny, and some of which persist throughout life, with little, if any, modification, as the *amoebocytes* of the adult sponge, while others become germ-cells, differentiated into ova and spermatozoa.

Amoebocytes.—These are amoeboid cells closely resembling the leucocytes or white blood corpuscles of higher animals. They commonly have blunt, lobose pseudopodia and the cytoplasm is generally more or less densely charged with refractive granules. They have the power of wandering from place to place through the mesogloea (fig. 34, 3–5).



(After Poléjaeff and Schulze.)

FIG. 37.—Spermatozoa.

a–h, Development of Spermatozoa in *Sycon raphanus*; *h*, Mature Spermatozoa; *j*, Sperm-ball in Mesogloea of *Oscarella lobularis*; *k*, Mature Spermatozoon.

Germ-Cells.—The ova (fig. 34, 6) are formed from amoebocytes, which grow to a large size and finally withdraw their pseudopodia and acquire a rounded form. They have large nuclei with a very distinct nuclear membrane and commonly a conspicuous nucleolus. The spermatozoa (fig. 37) closely resemble those of higher animals, consisting each of a small "head," composed chiefly of chromatin material, and a slender vibratile "tail" composed of cytoplasm. In this case the amoebocyte gives rise to a single sperm mother-cell (spermatocyte) sometimes enclosed in one or two covering cells. The nucleus of the spermatocyte undergoes repeated mitosis and a "sperm-ball" is produced which is either enclosed in the covering cell or in a special endothelium similar to that which surrounds the segmenting ovum. The germ-cells occur scattered through the mesogloea and are not aggregated in gonads, so that we cannot speak of "ovaries" and "testes" as in higher types.

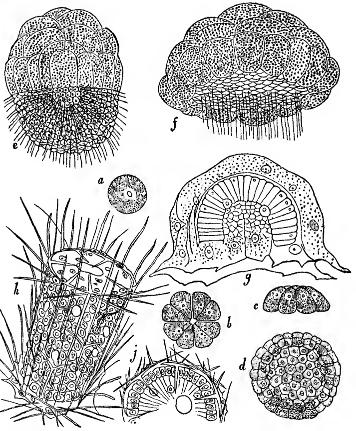
Reproduction.

Reproduction in sponges may be effected in one of three ways: (1) The first is by vegetative budding, followed by separation of the buds and thus differing from the ordinary budding which leads merely to increase in the size of the sponge-colony. This process has been observed in many cases (e.g. *Leucosolenia*, *Oscarella*, *Lophocalyx*, *Aplysilla*). (2) The second way is by the formation of specialized reproductive bodies known as *gemmules*. This process is best known in the fresh-water sponges (Spongillinae), where it has been developed as a special means of tiding over unfavourable periods during which the parent sponge is liable to be destroyed by cold or drought. Each gemmule consists of an aggregation of amoeboid cells (statocytes) densely charged with nutrient granules and enclosed in a protective horny envelope which may be strengthened by a layer of special spicules. The ripe gemmule is very resistant to adverse conditions and is capable of remaining dormant for a lengthened period, and of developing into a new sponge on the return of favourable conditions. In temperate climates the gemmules remain dormant throughout the winter and develop in the spring, the development being very similar to that of an ordinary fertilized ovum except that it begins at the "morula" stage, with the numerous statocytes representing the blastomeres. (3) The third way is by the union of ova and spermatozoa to form *zygotes*, which undergo segmentation and develop into the adult through a more or less complex series of ontogenetic stages. Previous to fertilization the ovum undergoes a process of maturation accompanied by the extrusion of two polar bodies, as in higher animals. Very little is known about the actual process of fertilization, but it appears probable that this is effected in the inhalant canals of the parent sponge, where the ova have been observed suspended from the epithelial lining of the canal (*e.g.* in *Ute*, fig. 34, 6). After fertilization they appear, usually at any rate, to migrate back into the mesogloea, where they become surrounded by endothelial capsules and undergo segmentation. In *Stelospongus flabelliformis* the cells of the capsule are of gigantic size and are attached to the superficial blastomeres of the developing embryo by protoplasmic processes, through which, no doubt, nutriment is passed from the parent to the embryo.

Embryology.

The segmentation of the ovum appears to be in all cases complete or holoblastic, and the young sponge usually leaves the parent in the form of a free-swimming ciliated larva, which, after fixing itself to some object, undergoes a metamorphosis and then grows into the adult form. The details of development appear to differ widely in different species and various interpretations have been placed upon somewhat limited and discrepant observations.

One of the best-known cases is that of the calcareous genus *Sycon* (fig. 38). The fertilized ova develop into ciliated larvae within the parent sponge, embedded in the walls of the radial chambers, in their endothelial capsules. Each divides first into two, then into four, and then into eight equal and similar blastomeres by successive vertical clefts. The eight-celled stage (fig. 38, *b*, *c*,) has the form of a somewhat flattened cushion, with an axial cavity which is the beginning of the blastocoel or segmentation cavity. A horizontal cleft now divides each blastomere into a somewhat smaller upper and a somewhat larger lower portion, and the sixteen blastomeres arrange themselves in the form of a hollow sphere surrounding the blastocoel. The smaller cells multiply rapidly and become columnar, while still remaining as a single layer. Each one presently acquires a flagellum ("cilium") at its outer end. The larger cells multiply more slowly and are characterized by their coarsely granular appearance. They are destined to give rise to the dermal layer and its derivatives (including archaeocytes ?) and never become flagellated.[1] The blastosphere or blastula (fig. 38, *d*, *e*,) is now complete, the blastocoel being completely surrounded by a single layer of cells differentiated, however, into two groups, gastral and dermal. The large granula (dermal) cells now become invaginated, but this is only a temporary condition, probably to be explained as the mechanical result of the pressure of the spicules of the parent sponge. The so-called "pseudogastrula" thus formed escapes by rupture



(After F. E. Schulze.)

[1] According to E. A. Minchin, the first-formed granular cells are "archaeocytes," which migrate into the interior of the larva while their place is taken by granular cells formed by modification of the neighbouring flagellated cells. The later-formed granular cells are destined to give rise to the dermal layer of the adult, while the remaining flagellated cells form the gastral layer.

of the parent tissues into a radial flagellated chamber and passes to the exterior with the outgoing stream of water. The invaginated dermal cells are pushed out again and the "amphiblastula" swims away (fig. 38, *e*). (Possibly the granular dermal cells, by proliferation, may form a solid mass blocking up the blastocoel completely, so that we have a solid embryo.) The larva now fixes itself by the anterior flagellated pole (which, according to Schulze, becomes permanently invaginated, thus giving rise to a true gastrula, fig. 38, *f*, *g*), and the dermal cells spread themselves out over the gastral cells, which they completely cover. The fixed larva ("pupa") consists of a solid mass of gastral cells enclosed in a single layer of now flattened dermal cells. Presently the gastral cavity appears (or reappears) in the middle, around which the gastral cells arrange themselves in a single layer. The young sponge elongates upwards, some of the dermal cells form porocytes which become perforated by prosopyles, others migrate into the gelatinous mesogloea and form scleroblasts, from which spicules are developed. The cells of the gastral layer acquire collars in addition to their flagella, an osculum is formed by perforation at the apex, and the young sponge begins to feed. It is now in the Olynthus condition (fig. 38, *h*) and is exactly comparable to a simple *Leucosolenia* individual. As it grows older radial flagellated chambers are budded out around the central gastral cavity and the collared cells lining the latter are replaced by pavement-epithelium derived from the dermal layer.

An interesting account of the development of *Leucosolenia* (*Clathrina*) *blanca* has been given by E. A. Minchin. Segmentation is regular and complete, resulting in the formation of a hollow, ciliated, oval blastula (fig. 39, *A*), with a large blastocoel and a wall composed of a single layer of columnar flagellated cells and a pair of very large granular cells at the posterior pole. The latter are primitive archaeocytes and are destined to give rise to the amoebocytes and germ-cells of the adult. The flagellated cells will give rise to all the other cells of the adult, both dermal and gastral. The larva becomes free-swimming in this condition. Here and there individual flagellated cells (destined to form the cells of the dermal layer) lose their flagella and, becoming amoeboid, migrate into the blastocoel, which presently becomes completely filled with such cells. The larva is thus converted into a solid "parenchymula," in which the archaeocytes remain unchanged in their original position at the posterior extremity. It now fixes itself and flattens out upon the substratum in the pupal condition. During the metamorphosis which now ensues the majority of the cells of the inner mass (dermal cells) pass out to the exterior again between the flagellated cells (gastral cells), over which they spread themselves in the form of a dermal layer of flattened epithelium. Some of the dermal cells, however, remain in the inner mass as porocytes; the primitive archaeocytes have divided up into amoebocytes; and porocytes, amoebocytes and the cells of the gastral layer are all crowded together in the interior of the pupa. The pupa now elongates vertically. A gastral cavity appears in the interior. The cells of the gastral layer arrange themselves around this cavity and develop their collars and flagella. At first, however, the gastral cavity is lined by the porocytes, which presently separate and migrate outwards.[1] Scleroblasts migrate inwards from the dermal layer and secrete spicules. An osculum and prosopyles are formed as in *Sycon* and the Olynthus stage is reached.

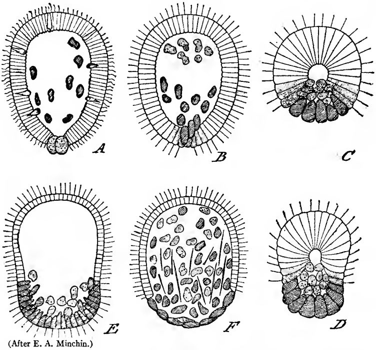
The development of sponges in general appears to be characterized by a remarkable want of uniformity in the arrangement of the different kinds of cells of which the larva is composed. Two, or possibly three, primary groups of cells are universally present; the flagellated cells, which will give rise to the collared cells of the adult, the non-flagellated (granular) cells, which will give rise to the dermal layer and its derivatives, and possibly the primitive archaeocytes (perhaps to be regarded as undifferentiated blastomeres). It may be considered as doubtful, however, whether the primitive archaeocytes can in all cases be distinguished from the primitive dermal cells. The latter are in some cases (amphiblastula type) grouped at the posterior pole of the larva (*Sycon*), while in other cases (parenchymula type) they may pass inwards and completely fill the interior, blocking up the blastocoel and perhaps also freely projecting at the hinder end (fig. 39, *F*). At the time of the metamorphosis the dermal cells pass to the outside and come to completely enclose the gastral cells, so that the two layers acquire their proper relative positions. The sponge larva in many respects closely resembles the Coelenterate "planula," with its ectoderm and endoderm, but it is very doubtful how far this comparison is valid, and in the present state of our knowledge it is perhaps better to avoid the use of the terms ectoderm and endoderm in dealing with the sponges altogether. The idea naturally suggests itself that the two primary layers of the Sponge correspond to those of the Coelenterate, but in a reversed position, the inner layer of the one being the outer layer of the other, and vice versa, and this idea has found expression in the name *Enantiozoa* which has been proposed for the group by Yves Delage, but which has not met with general acceptance.

Physiology.

Comparatively little is known of the physiology of sponges. The most obvious expression of the vital activity of the organism is the stream of water which flows in through the dermal pores or ostia and out through the vents or oscula. That this stream is maintained by the undulatory movements of the flagella of the collared cells there can be no doubt, but the fact that the movements of the flagella of different cells are not co-ordinated, so that they do not act in unison, indicates that the mechanical problem involved is not so simple as is usually supposed. There can be no doubt that the incoming stream brings with it minute food-particles, consisting of fragments of organic matter, alive or dead, and also the oxygen required for purposes of respiration; while the outgoing stream removes faecal products and waste matter (excreta). The rate of flow appears to be regulated by the opening and closing of the pores and vents, or of intermediate apertures such as the apopyles or exhalent openings of the flagellate chambers. This opening and closing may be effected by the activity of definite muscular sphincters (fig. 34, 2) or, in the case of some prosopyles, by the contractility of the porocytes themselves.

The ingestion of the food particles is no doubt effected in large measure by the collared cells, which seem to feed much in the same manner as independent collared monads (Choanoflagellata). It seems not improbable that Sollas's membrane may be a temporary structure which assists in arresting food particles as they pass through the flagellate chambers. There is reason to believe also that amoebocytes (in this case therefore phagocytes) may capture minute organisms on their way through the canal system, and even porocytes are sometimes credited with this power. Digestion, no doubt, is, at any rate chiefly, intracellular. The amoebocytes probably serve not only to ingest food themselves but also to receive surplus food from the collared cells and distribute it through the sponge (fig. 34, 5).

Nothing definite is known as to the function of excretion, but here, as in the case of nutrition, it seems likely that collared cells and amoebocytes are both concerned.



(After E. A. Minchin.)

FIG. 39.—Types of Sponge Larvae (semi-diagrammatic). The ciliated (gastral) cells are left blank; the dermal cells are shaded, and the archaeocytes are granulated.

A, Larva of *Leucosolenia* (*Clathrina*) *blanca*.

D, Late larva of *Leucosolenia* (or newly hatched larva of *Sycon*).
E, Larva of *Oscarella*.
F, Parenchymula larva of a siliceous Monaxonellid (*Myxilla*).

[1] The position of the porocytes inside the collared cells appears at first sight very anomalous, but Minchin has shown that this condition is actually repeated in the adult sponge every time the gastral cavity is obliterated by contraction.

Sponges, as we have already seen possess no special nervous system and no special sense organs, and the power of response to stimuli appears to be very limited. Many sponges probably have the power of contracting as a whole, which may in some cases be due, in part at any rate, to the presence of bands of muscular fibres, and Sollas observes that in *Pachymatisma* irritation of the oscular margin is invariably followed after a short interval by a slow closure of the sphincter. The power of movement in adult sponges is, however, chiefly confined to individual cells acting independently. The young larvae, on the other hand, swim vigorously about by means of their cilia or flagella, whose movements must obviously be co-ordinated in order to ensure the progress of the entire organism in definite directions.

The rate of growth of sponges appears to be very rapid. A British species of *Hymeniacidon* is said to form a crust measuring a foot in diameter in so short a period as five months. With this rapidity of growth must be associated the fact that many sponges, marine as well as fresh-water, appear to be annual.

Distribution.

The vast majority of sponges are marine, only a single sub-family, the Spongillinae, having acquired the habit of living in fresh water. The Spongillinae are, however, very widely distributed, being found in lakes and rivers in all parts of the world. Marine sponges occur everywhere, from low-water mark to the greatest depths, but certain localities, such as the Gulf of Manaar, Port Phillip and Port Jackson, appear to be much richer than others both in individuals and species. The Hexactinellida are essentially a deep-water group and are therefore much more rarely met with than other forms. The Tetraxonida and Euceratosa abound in shallow and in moderately deep water, and a comparatively small number of species of Tetraxonida occur at great depths. Both are dominant groups at the present day, represented by very large numbers of species and individuals. The Myxospongida are comparatively rare and represented by very few species. The Calcarea are common in the littoral region, especially in sheltered situations amongst rocks and seaweed.

Most families and even genera of sponges enjoy a very wide geographical range, very many being cosmopolitan. Species are usually much more restricted in distribution, but even here there are some noteworthy exceptions, and future researches will probably show that many species from different localities which are at present regarded as distinct are connected by intermediate forms living in intermediate situations.

There appears to be a well-marked relation between temperature and the power of spongin-secretion, and as a result we find that sponges with a really well-developed horny skeleton (whether *Euceratosa* or *Pseudoceratosa*) are usually only met with in comparatively warm waters. This fact brings about a striking contrast between the sponge-faunas of different latitudes.

Classification.

The classification of the Phylum Porifera, the characters of which have already been given, is as follows:—

Sub-phylum and Class **Calcarea.**—Sponges with a skeleton composed of carbonate of lime, commonly in the form of isolated spicules whose most usual shape is triradiate.

Order 1. Homocoela.—Calcarea in which the gastral cavity and its outgrowths are lined throughout by collared cells. This order is sometimes divided into two families, Clathrinidae and Leucosoleniidae, but it is doubtful if this distinction can be maintained, and by some writers only a single genus (*Leucosolenia*) is recognized.

Order 2. Heterocoela.—Calcarea in which the original lining of the gastral cavity is partly replaced by pavement epithelium, so that the collared cells are confined to separate flagellated chambers. This order includes the living families Leucascidae, Sycettidae, Grantidae, Heteropidae, Amphoriscidae and Pharetronidae (with only two living representatives but numerous fossil forms). The relationships of the anomalous *Astrosclera* (fig. 25), for which the family *Astroscleridae* has been proposed by J. J. Lister, must still be regarded as problematical.

Sub-phylum **Non-Calcarea.**—Sponges without any calcareous skeleton.

Class and Order Myxospongida.—Sponges with no skeleton; with simple canal system and usually large flagellate chambers. (The absence of skeleton is primitive and not due to degeneration.) This class is sometimes divided into two families—Halisarcidae, with elongated, sac-shaped chambers, and Oscarellidae, with more or less spherical chambers.

Class Triaxonida (=Hexactinellida).—Sponges with a skeleton composed of siliceous spicules, either isolated or cemented together by silica, and either triaxonid and hexactinellid in form or derivable from the triaxonid and hexactinellid type. The canal system is simple and the flagellated chambers are large and sac-shaped, and more or less radially arranged in a network of trabecular tissue. Spongin is never formed.

Order 1. Amphidiscophora.—Triaxonida with characteristic amphidisc spicules, but no hexasters, and with a root-tuft of anchoring spicules. The family Hyalonematidae, including the well-known glass-rope sponges of the genus *Hyalonema*, is the only family recognized in this order.

Order 2. Hexasterophora.—Triaxonida whose most characteristic spicules are hexasters. To this order belong the living families Euplectellidae, Asconematidae, Rossellidae, Euretidae, Melittionidae, Coscinoporidae, Tretodictyidae and Macandrospongidae, and a number of extinct families such as the *Ventriculitidae* so commonly met with in the Jurassic and Cretaceous rocks.

Class Tetraxonida.—Sponges with a skeleton composed of siliceous spicules, either isolated or cemented together (by silica or by spongin), and either tetraxonid and tetractinellid in form or derivable from the tetraxonid and tetractinellid type. The canal system is usually complex, with small, more or less spherical flagellated chambers.

Grade Tetractinellida.—Tetraxonida in which some, at any rate, of the megascleres retain the primitive tetractinellid form. No desmas are developed.

Order 1. Homosclerophora.—Tetractinellida in which microscleres and megascleres are not yet sharply differentiated from one another and no triaenes are developed. The canal system is comparatively simple. This order includes the family Plakinidae (see *Plakina, ante*) which forms the starting-point of the evolution of the class.

Order 2. Astrophora.—Tetractinellida with triaenes and with astrose microscleres, without sigmata. This order includes the families Pachastrellidae, Theneidae, Stellettidae, Geodiidae.

Order 3. Sigmatophora.—Tetractinellida with triaenes, with sigmata for microscleres (when present), without asters. This order includes the families Tetillidae and Samidae.

Grade (? order) Lithistida.—Tetraxonida in which the megascleres form desmas, typically united with each other by siliceous cement to form a continuous skeleton, often of stony hardness. This group includes both tetractinellid and monaxonellid forms and may possibly be of polyphyletic origin. The Lithistida bear the same relation to the other Tetraxonida that the dictyonine Hexactinellids bear to the lyssacine forms, but in the present state of our knowledge it is hardly possible to trace the natural affinities of the numerous members of the group, many of which are only known in the fossil state. The following are the principal families: Tetracladidae, Desmanthidae, Corallistidae, Pleromidae, Neopeltidae, Scleritodermidae, Cladopeltidae, Azoricidae, Anomocladidae.

Grade Monaxonellida.—Tetraxonida in which the primitive tetraxonid and tetractinellid condition of the megascleres has been entirely lost through suppression of some of the spicule rays, so that none but monaxonellid megascleres remain. No desmas are developed. Owing to the extreme reduction or modification of the skeleton, leading in many cases to convergence, the classification of this group is extraordinarily difficult and the group is obviously not monophyletic.

Order 1. Astromonaxonellida.—Monaxonellida in which the microsclere, when present, is some form of aster. The members of this order are to be regarded as descended from aster-bearing tetractinellid ancestors.

Families.—Epipolasidae, Tethyidae, Spirastrellidae (including Placospongiidae), Clionidae (the boring sponges), Suberitidae, Chondrosiidae. (In *Chondrosia* the skeleton is entirely suppressed, so that it simulates the Myxospongida.)

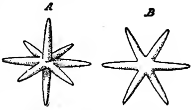
Order 2. Sigmatomonaxonellida.—Monaxonellida in which the typical microscleres are sigmata, or other diactinal forms. Normal astrose microscleres are absent (though secondary pseudasters are occasionally present). The members of this order are to be regarded as descended from sigma-bearing tetractinellid ancestors.

Families.—Haploscleridae (chief sub-families: Gelliinae, Renierina Chalininae, Spongillinae), Desmacidonidae (chief sub-families: Esperellinae, Ectyoninae), Axinellidae.

Class and Order Euceratosa.—Non-calcareous sponges without siliceous spicules, but with a skeleton composed of horny fibres developed independently, *i.e.* not in relation to any pre-existing spicular skeleton. The skeleton is often supplemented, or even largely replaced, by foreign bodies. This group includes the bath-sponges and their very numerous relations.

Families.—Aplysillidae, Spongeliidae, Spongiidae.

There are two groups of palaeozoic fossil siliceous sponges which apparently do not fit into the above system, viz. the Octactinellida and Heteractinellida of G. J. Hinde. The former, represented by the genus *Astraeospongia*, have octactinal megascleres. The latter, represented by the genera *Tholiasterella* and *Asteractinella*, have polyaxon megascleres with an indefinite number of rays. These may indicate the former existence of two distinct classes of siliceous sponges



(After G. J. Hinde.)

which are, so far as we know, totally unrepresented at the present day.

Phylogeny.

The most recent views as to the evolution and inter-relationships of the principal groups of sponges above enumerated may be conveniently expressed by the accompanying phylogenetic tree (fig. 42). Starting with the hypothetical Protolynthus as the ancestral form of the entire group, we see how two divergent lines of descent are very early established according to whether or not a calcareous skeleton is developed. The Calcarea are at first simple Olynthus forms, Homocoela, differing only from the Protolynthus in the presence of the calcareous spicules. From these are derived, by the process of budding, on the one hand reticulate forms (*Clathrina*) and on the other radiate forms (*e.g. Leucosolenia tripodifera*), and some of the latter (now probably extinct) form the starting point for the evolution of the Calcarea Heterocoela, beginning with simple Syconoid forms and ending with complex Leuconoids, in which the original process of simple budding has been followed up by elaborate modifications of both skeleton and canal system.

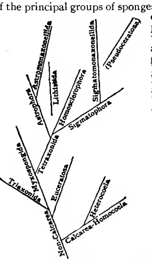

FIG. 42.—Phylogenetic Tree, showing the supposed relationships of the principal groups of sponges to one another.

Turning to the other main line of descent we find at once a conspicuous gap between the Protolynthus and the simplest known non-calcareous sponge; though the analogy of the Calcarea makes it easy to understand how the almost Syconoid canal system of the simplest Hexactinellids, or the primitive Rhagon type of other groups, may have been derived from the Protolynthus ancestor in the first instance by simple budding. This line of descent may be regarded as continued straight on into the existing Myxospongida, with increase in the complexity of the canal system, due to folding of the chamber-bearing layer and the accompanying development of inhalent and exhalent canal systems, but without the development of any skeleton. The Triaxonida and Euceratosa would seem to have branched off independently at a very early stage from the Myxosponge line, before the flagellated chambers had suffered that reduction in size which occurs in some existing Myxospongida and in all Tetraxonida. In the Triaxonid line of descent the evolution of the siliceous skeleton of primitively hexactinellid spicules is the leading feature, the canal system preserving remarkable uniformity throughout the group. In the Tetraxonida also the skeleton has played the principal part in the evolution of existing species, but the canal system too has undergone great modifications. The primitive tetraxonid, tetractinellid siliceous spicules must have arisen quite independently, their fundamental form being totally different from that of the triaxonid hexactinellid type. The appearance of differentiated microscleres in this group introduced new possibilities of variation, of which full advantage has been taken, and we are confronted with most interesting evolutionary series, terminating in many very remarkable and at present inexplicable spicule forms (fig. 29). In many of the more advanced Tetraxonida, especially in the Chalininae, the development of spongin cement also appears as a new factor in the process of evolution. At first serving merely to glue the megascleres together into a continuous framework, it ultimately, in some extreme cases, completely replaces the siliceous skeleton and gives rise to a purely "horny" skeleton in which all traces of spicules have been lost by degeneration. Thus we arrive at a "Pseudoceratose" condition (fig. 32, *D*) which must be carefully distinguished from the condition of the Euceratosa, which have apparently branched off quite independently from Myxosponge ancestors. Here we have another typical example of that phenomenon of "convergence" which has rendered the classification of sponges so very difficult. In the Euceratose line of descent we start with forms (*Aplysilla*) with large sac-shaped chambers and altogether primitive canal system, accompanied by an arborescent horny skeleton (fig. 33) of an entirely different type from that of the pseudoceratose Tetraxonida. From this we can trace the evolution gradually through the Spongeliidae to the Spongiidae, the skeleton becoming reticulate and the canal system gradually more complex with accompanying reduction in size of the chambers. The bath sponge perhaps represents the culminating point in this direction. Thus it appears that both the horny type of skeleton and the siliceous spicular type have been twice independently produced in the evolution of the Non-calcarea. An analogous case of convergence is seen in the union of originally separate spicules into a coherent skeleton by means of cement of the same chemical composition as themselves. This has taken place independently in the Calcarea (*Petrostoma*), the Dictyonine Hexactinellida and the Lithistid Tetraxonida.

Affinities of the Porifera.

Three main views have been put forward with regard to the position of the Sponges in the animal kingdom: (1) that they are colonies of Protozoa; (2) that they form a subdivision of the Coelenterata; (3) that they are not Protozoa but have originated from Protozoon ancestors quite independently from other Metazoa (Enterozoa). The first of these views, associated especially with the names of James Clark and Saville Kent, is supported by the relative independence of the constituent cells in the sponge-body and by the extraordinary resemblance of the collared cells to the choanoflagellate or collared Monads. It is also supported by the existence of a remarkable colonial form of Choanoflagellata (*Proterospongia*) in which the collared Monads are partially embedded in the surface of a gelatinous matrix, in the interior of which amoeboid cells are found. E. A. Minchin has shown that even in the adult *Leucosolenia* (*Clathrina*) the collared cells and porocytes have the power of changing their relative positions, while migration of dermal and gastral cells and consequent inversion of the layers appears to be a common feature of the sponge larva at the time of metamorphosis. These facts are certainly suggestive of Protozoon colonies rather than of Metazoa. On the other hand it must not be forgotten that migratory amoebocytes (*leucocytes*) occur in probably all groups of Metazoa, while the degree of integration and the amount of histological differentiation in Sponges are far greater than in any other Protozoon colonies known to us. It has been argued that the process of sexual reproduction by means of ova and spermatozoa is fatal to the Protozoon-colony theory, but this argument is completely disposed of by the discovery of spermatozoa and ova in the unicellular Sporozoa. On the other hand the occurrence of collared cells has been held to distinguish the Sponges from all other Metazoa, and this argument has also been answered by the discovery of collared cells in the larva of *Echinocyamus* (an Echinoderm) by H. Theel. It would, in short, be difficult to frame a definition of the Protozoa which should absolutely exclude the Sponges, while at the same time our conception of the nature of Protozoa will have to be profoundly modified if we are to admit the Sponges within the limits of that group.

The second view, that the Sponges constitute a subdivision of the Coelenterata, is maintained by some very eminent continental authors such as Ernst Haeckel and F. E. Schulze. This view is supported by the structure of the Olynthus type, which, as we have seen, forms the starting-point of Sponge evolution. The dermal layer of the Olynthus is regarded as ectoderm, the gastral layer as endoderm and the mesogloea with its contained cells as mesoderm, more highly developed than in most Coelenterates. It is also supported by a considerable amount of agreement in the early stages of development, up to the formation of the ciliated larva. According to this view the Olynthus, or at any rate the imaginary "*Protolynthus*" is only a slightly modified gastrula, and the Sponges are therefore Enterozoa without any coelom, or in other words Coelenterata. The extraordinary histological differences between the Sponges and other Coelenterates (Cnidaria), combined with the highly characteristic canal system and the absence of tentacles, are, however, alone sufficient to throw grave doubts upon the probability of a close relationship between the two groups, and these doubts are greatly strengthened by recent embryological researches, which tend to show that the so-called ectoderm and endoderm are not homologous in the two cases.

There remains the third view, in accordance with which the Sponges are multicellular animals which have originated quite independently from Choanoflagellate Protozoon ancestors, and this is the view which at present seems to have most in its favour. It is especially associated with the name of W. J. Sollas, who invented the term "Parazoa" for the group. In support of this view it may be pointed out that the tendency to form hollow, spherical colonies, resembling the blastosphere stage in the development of Enterozoa, is met with in very distinct groups of Protozoa (e.g. *Volvox*, *Sphaerozoum*). This form of colony is obviously polyphyletic in origin. The fact that the segmentation of the ovum leads to such a form in both Sponges and Enterozoa is therefore by no means conclusive evidence that Sponges and Enterozoa have originated from the same Protozoon group. While, as has been repeatedly pointed out, the universal and characteristic collared cells of sponges point emphatically to a Choanoflagellate ancestry, it is impossible, in the present state of our knowledge, to indicate the particular Protozoon group which has given origin to the Enterozoa. We may then consider the Metazoa, or many-celled animals, as a polyphyletic, or at any rate diphyletic group, including two perfectly distinct lines of descent from the ancestral Protozoa, the Sponge-line on the one hand, which leads to nothing higher than Sponges, which retain in many respects the characters of Protozoa, and the Enterozoon line on the other, which leads through the Coelenterata to the Coelomata and so on to the highest divisions of the animal kingdom.

Economics.

All the bath sponges belong to the two genera *Euspongia*, Bronn, and *Hippospongia*, Schulze, subdivisions of the old genus *Spongia*, auctorum, distinguished from one another by the fact that in *Hippospongia* the body of the sponge is traversed by wide ramifying canals or vestibules, in addition to the proper canal system of the sponge. Species of these two genera occur in many parts of the world, probably wherever the temperature of the sea-water is sufficiently high and the depth and bottom suitable. It is only in a few localities, however, that they occur in sufficient numbers and of sufficiently good quality to render a sponge fishery practicable. The sponges of commerce are obtained chiefly from the Mediterranean, the coast of Florida and the Bahama Islands. From the Mediterranean three distinct species are obtained—(1) *Euspongia officinalis*, which includes the "fine sponges," with two chief varieties, *mollissima* (the Levantine sponges, very soft and often cup-shaped), and *adriatica*; (2) *Euspongia zimocca*, including the "hard" or Zimocca sponges; (3) *Hippospongia equina*, the "common" or "horse" sponge.

Of the Florida sponges five principal kinds are recognized by the dealers—(1) the sheep's wool sponge (*Hippospongia gossypina*)—this appears to be by far the most abundant in the market and also the most valuable; (2) the yellow sponge (*Euspongia agaricina*), resembling the Zimocca sponge of the Mediterranean; (3) the grass sponges (including both *Hippospongia graminea* and *H. cerebriformis*); (4) the velvet sponge *Hippospongia maeandriniformis*), which is not so common as the others; (5) the glove sponge (*Euspongia tubulifera*), which is the least valuable. In the year 1900 the Florida sponge fisheries yielded 418,125 ℔ of sponges, valued at $567,685. The Bahama sponges appear to be very similar to those of Florida.

Bath sponges occur in comparatively shallow water and are obtained by diving, by dredging, or by means of a trident or long-handled fork. The preparation of the sponges for the market is extremely simple. The slimy soft tissues very soon begin to decay and run off when they are removed from the water; after this has gone on for some time the sponges are washed and beaten until the skeleton is clean, they are then threaded on string and dried. They are frequently "loaded" with foreign matter by the dealers in order to increase their weight; rock-salt, glucose, molasses, lead, gravel, sand and stones being used for the purpose. They are also often bleached by means of chemicals to give them a better colour, but though their appearance is thereby greatly improved, their durability is said to be impaired.

In spite of the undoubted rapidity with which sponges grow, as shown by the fact that on the coast of Florida marketable sponges are found commonly in places that had been stripped of saleable specimens in the preceding year, there appears to be considerable danger of injury to the sponge industry by over-fishing and by the reckless destruction of young specimens, and it has been found necessary to introduce special legislation in America to counteract these evil tendencies. The question of the artificial propagation and cultivation of sponges has also been much discussed, but although some very interesting experiments have been made, they have not as yet led to any great practical results. As far back as 1862 Oscar Schmidt showed that "cuttings" of sponges will attach themselves and grow. This idea was followed out in the experiments of G. Buccich on the Island of Lesina, from 1863–1872, but these experiments were brought to a close by the hostility of the native fishermen. Similar experiments have since been made on the Florida sponge-grounds. The possibility of rearing sponges in this way from cuttings has thus been fully demonstrated, but whether it can be done profitably is another question. According to the experience of G. Buccich it appeared that it would take seven years for the cuttings to attain marketable size in the Mediterranean. The Florida experiments, on the other hand, indicate a much more rapid rate of growth, and it has been stated that under favourable conditions the cuttings will attain marketable size in as short a time as one year. It has been doubted, however, whether the total weight of sponges produced by cuttings would be greater than the weight of the sponges from which the cuttings were taken if these sponges were allowed to continue their growth undisturbed. H. V. Wilson has suggested that sponges may be artificially reared from the eggs, in the same way that fishes or oysters are reared. The eggs of the bath sponge, like those of other sponges, develop into free-swimming ciliated larvae, and these might be made to attach themselves, like oyster-spat, to suitable objects, on which the young sponges could be cultivated under appropriate conditions. Detailed experiments are required to demonstrate the feasibility or otherwise of this interesting suggestion.

For further information on the economic aspect of the subject the student should consult the annual Bulletin and special papers of the United States Bureau of Fisheries and also the work of Seurat referred to in the bibliography.

Bibliography.—A very full list of the literature of the group up to 1889 is given in Lendenfeld's work on the Horny Sponges, published by the Royal Society. We have only space here to refer to a very limited number of memoirs. Other references will be found in the works cited.

SPONSOR (from Lat. *spondere*, to promise), one who stands surety for another, especially in the rite of Christian baptism, a godfather or godmother. The practice originated not in infant baptism, but in the custom of requiring an adult pagan who offered himself for the rite to be accompanied by a Christian known to the bishop, who could vouch for the applicant and undertake his supervision, thus fulfilling the function performed in the Eleusinian mysteries by the *mystagogus*. The Greek word for the person undertaking this function is ἀνάδοχος, to which the Latin *susceptor* is equivalent. The word "sponsor" in this ecclesiastical sense occurs for the first time, but incidentally only, and as if it were already long familiar, in Tertullian's treatise *De baptismo* (ch. 18), where, arguing that in certain circumstances baptism may conveniently be postponed, especially in the case of little children, he asks, "For why is it necessary that the sponsors likewise should be thrust into danger, who both themselves by reason of mortality may fail to fulfil their promises, and may also be disappointed by the development of an evil disposition [in those for whom they become sponsors]?" The sponsors here alluded to may have been in many cases the actual parents, and even in the 5th century it was not felt to be inappropriate that they should be so; Augustine, indeed, in one passage appears to speak of it as a matter of course that parents should bring their children and answer for them "tanquam fidejussores" (*Epist. . . . ad Bonif.* 98), and the oldest Egyptian ritual bears similar testimony. Elsewhere Augustine contemplates the bringing of the children of slaves by their masters, and of course orphans and foundlings were brought by other benevolent persons. The comparatively early appearance, however, of such names as *compatres*, *commatres*, *propatres*, *promatres*, *patrini*, *matrinae*, is of itself sufficient evidence, not only that the sponsorial relationship had come to be regarded as a very close one, but also that it was not usually assumed by the natural parents. How very close it was held to be is shown by the Justinian prohibition of marriage between godparents and godchildren. On the other hand, the anciently allowable practice of parents becoming sponsors for their own children, though gradually becoming obsolete, seems to have lingered until the 9th century, when it was at last formally prohibited by the council of Mainz (813). For a long time there was no fixed rule as to the necessary or allowable number of sponsors and sometimes the number actually assumed was large. By the council of Trent, however, it was decided that one only, or at most two, these not being of the same sex, should be permitted. The rubric of the Church of England according to which "there shall be for every male child to be baptized two godfathers and one godmother, and for every female one godfather and two godmothers," is not older than 1661; the sponsors are charged with the duty of instructing the child, and in due time presenting it for confirmation, and in the Catechism the child is taught to say that he received his name from his "godfathers and godmothers." At the Reformation the Lutheran churches retained godfathers and godmothers, but the Reformed churches reverted to what they believed to be the more primitive rule, that in ordinary circumstances this function should be undertaken by a child's proper parents. Most churches demand of sponsors that they be in full communion. In the Roman Catholic Church, priests, monks and nuns are disqualified from being sponsors, either "because it might involve their entanglement in worldly affairs," or more probably because every relationship of fatherhood or motherhood is felt to be in their case inappropriate. The spiritual relationship established between the sponsor and the baptized, and the sponsors and the parents of the baptized, constitutes an impediment to marriage (see Marriage: *Canon Law*).

SPONTINI, GASPARO LUIGI PACIFICO (1774–1851), Italian musical composer, was born on the 14th of November 1774 at Majolati (Ancona) in Italy. He was the son of a poor cobbler and was intended for the priesthood. His musical propensities however were not to be restrained, and he obtained lessons from Kapellmeister Quintiliani. In 1791 he went to the Conservatorio de' Turchini at Naples, where he was trained to write operatic music under Paisiello, Cimarosa and Fiorivanti. His first opera, *L'Eroismo ridicolo*, was successfully produced in 1796, and by 1799 he had already written and produced eight operas. After becoming court composer to King Ferdinand of Naples in this year an intrigue with a princess of the court compelled Spontini to leave Naples in 1800. For the next few years he wrote operas in Rome and Venice until 1803 when he settled in Paris, where his reception was anything but flattering. His comic opera *Julie* proved a failure; a successor, *La Petite maison*, was hissed. Undaunted by these misfortunes, he abandoned the light and somewhat frivolous style of his earlier works, and in *Milton*, a one-act opera produced in 1804, achieved a real success. Spontini henceforth aimed at a very high ideal, and during the remainder of his life strove so earnestly to reach it that he frequently remodelled his passages five or six times before permitting them to be performed in public, and wearied his singers by introducing new improvements at every rehearsal. His first masterpiece was *La Vestale*, completed in 1805, but kept from the stage through the opposition of a jealous clique until the 15th of December 1807, when it was produced at the Académie, and at once took rank with the finest works of its class. Spontini had abandoned the *parlando* of Italian opera for an accompanied recitative; he had increased the strength of the orchestra and introduced the big chorus freely. His opera, *Ferdinand Cortez*, was received with equal enthusiasm in 1809; but another, *Olympia*, was much less warmly welcomed in 1819. Napoleon, whose approval of any work of art was at once a compliment to the artist and a serious imputation on the value of the work, professed immense admiration for Spontini's music.

Spontini had been appointed director of the Italian opera in 1810; but his quarrelsome and grasping disposition led to his summary dismissal two years later, and, though reinstated in 1814, he voluntarily resigned his post soon afterwards. He was in fact very ill fitted to act as director; yet on the 28th of May 1820, five months after the failure of *Olympia*, he settled in Berlin by invitation of Frederick William III., commissioned to superintend all music performed at the Prussian court and compose two new grand operas, or three smaller ones, every three years. But he began by at once embroiling himself with the intendant, Count Brühl. Spontini's life at Berlin may be best described as a ceaseless struggle for precedence under circumstances which rendered its attainment impossible. Yet he did good work. *Die Vestalin*, *Ferdinand Cortez* and *Olympia*—the last two entirely remodelled—were produced with great success in 1821. A new opera, *Nourmahal*, founded on Moore's *Lalla Rookh*, was performed in 1822, and another, entitled *Alcidor*, in 1825; and in 1826 Spontini began the composition of *Agnes von Hohenstaufen*, a work planned on a grander scale than any of his former efforts. The first act was performed in 1827, and the complete work in three acts graced the marriage of Prince William in 1829. Though the German critics abused it bitterly, *Agnes von Hohenstaufen* is undoubtedly Spontini's greatest work. In breadth of conception and grandeur of style it exceeds both *Die Vestalin* and *Ferdinand Cortez*, and its details are worked out with untiring conscientiousness. Spontini himself, however, was utterly dissatisfied with it, and at once set to work upon an entire revision, so that on its re-presentation in 1837 many parts were scarcely recognizable by those who had heard the opera in its original form.

This was his last great work. He several times began to rewrite his early opera, *Milton*, and contemplated the treatment of many new subjects, such as *Sappho*, *La Colère d'Achille*, and other classical myths, but with no definite result. He had never been popular in Berlin; and he has been accused of endeavouring to prevent the performance of *Euryanthe*, *Oberon*, *Die Hochzeit des Camacho*, *Jessonda*, *Robert the Devil*, and other works of genius, through sheer envy of the laurels won by their composers. But the critics and reviewers of the period were so closely leagued against him that it is difficult to know what to believe. After the death of Frederick William III. in 1840 Spontini's conduct became so violent and imperious that he was sentenced to nine months' imprisonment for *lèse-majesté*. The sentence was remitted by Frederick William IV., but on the 2nd of April 1841, when he appeared at the conductor's desk to direct a performance of *Don Juan*, he was greeted with hisses and groans, and his orders to raise the curtain were ignored, so that he was compelled to leave the desk. The king dismissed him on the 25th of August, with power to retain his titles and live wherever he pleased in the enjoyment of his full salary. He elected to settle once more in Paris, after a short visit to Italy; but beyond conducting occasional performances of some of his own works he made but few attempts to keep his name before the public. In 1847 he revisited Berlin and was invited by the king to conduct some performances during the winter. In 1848 he became deaf. In 1850 he retired to his birthplace, Majolati, and died there on the 14th of January 1851, bequeathing all he possessed to the poor of his native town.

SPONTOON (Fr. *esponton*, Ital. *spontone*, from Lat. *punctum*, point, *pungere*, to prick), a weapon carried by infantry officers in the 17th and early 18th centuries. It was a type of the partisan or halberd (*q.v.*), a shafted weapon with a special form of spear head.

SPOON (O. Eng. *spōn*, a chip or splinter of wood, cf. Du. *spaan*, Ger. *Spahn*, in same sense, probably related to Gr. σφήν, wedge), a table implement, bowl-shaped at the end, with a handle varying in length and size. From the derivation of the word the earliest northern European spoon would seem to have been a chip or splinter of wood; the Greek κοχλιάριον (Lat. *cochleare*) points to the early and natural use of shells, such as are still used by primitive peoples. Examples are preserved of the various forms of spoons used by the ancient Egyptians of ivory, flint, slate and wood, many of them carved with the symbols of their religion. The spoons of the Greeks and Romans were chiefly made of bronze and silver, and the handle usually takes the form of a spike or pointed stem. There are many examples in the British Museum from which the form of the various types can be ascertained, the chief points of difference being found in the junction of the bowl with the handle. Medieval spoons for domestic use were commonly made of horn or wood, but brass, pewter and "latten" spoons appear to have been common about the 15th century. The full descriptions and entries relating to silver spoons in the inventories of the royal and other households point to their special value and rarity. The earliest English reference appears to be in a will of 1259. In the wardrobe accounts of Edward I. for the year 1300 some gold and silver spoons marked with the fleur-de-lis, the Paris mark, are mentioned. One of the most interesting medieval spoons is the coronation spoon used in the anointing of the sovereign, an illustration of which is given under REGALIA. The sets of spoons popular as christening presents in Tudor times, the handles of which terminate in heads or busts of the apostles, are a special form to which antiquarian interest attaches (see APOSTLE SPOONS). The earlier English spoon-handles terminate in an acorn, plain knob or a diamond; at the end of the 16th century the baluster and seal ending becomes common, the bowl being "fig-shaped." At the Restoration the handle becomes broad and flat, the bowl is broad and oval and the termination is cut into the shape known as the *pied de biche*, or hind's foot. In the first quarter of the 18th century the bowl becomes narrow and elliptical, with a tongue or "rat's tail" down the back, and the handle is turned up at the end. The modern form, with the tip of the bowl narrower than the base and the rounded end of the handle turned down, came into use about 1760.

See C. J. Jackson, "The Spoon and its History," in *Archaeologia* (1892), vol. liii.; also Cripps, *Old English Plate*.

SPOONBILL. The bird now so called was formerly known in England as the Shovelard or Shovelar, while that which used to bear the name of Spoonbill, often amplified into Spoon-billed Duck, is the Shoveler (*q.v.*) of modern days—the exchange of names having been effected as already stated (*loc. cit.*) about 200 years ago, when the subject of the present notice—the *Platalea leucorodia* of Linnaeus as well as of recent writers—was doubtless far better known than now, since it evidently was, from ancient documents, the constant concomitant of Herons, and with them the law attempted to protect it.[1] J. E. Harting (*Zoologist*, 1886, pp. 81 seq.) has cited a case from the "Year-Book" of 14 Hen. VIII. (1523), wherein the then bishop of London (Cuthbert Tunstall) maintained an action of trespass against the tenant of a close at Fulham for taking Herons and "Shovelars" that made their nests on the trees therein growing, and has also printed (*Zoologist*, 1877, pp. 425 seq.) an old document showing that "Shovelars" bred in certain woods in west Sussex in 1570. Nearly one hundred years later (*c.* 1662) Sir Thomas Browne, in his "Account of Birds found in Norfolk" (*Works*, ed. Wilkin, iv. 315, 316), stated of the "*Platea* or *Shouelard*" that it formerly "built in the Hernerie at Claxton and Reedham, now at Trimley in Suffolk." This last is the latest known proof of the breeding of the species in England; but more recent evidence to that effect may be hoped for from other sources. That the Spoonbill was in the fullest sense of the word a "native" of England is thus incontestably shown; but for many years past it has only been a more or less regular visitant, though not seldom in considerable numbers, which would doubtless, if allowed, once more make their home there; but its conspicuous appearance renders it an easy mark for the greedy gunner and the contemptible collector. What may have been the case formerly is not known, except that, according to P. Belon, it nested in his time (1555) in the borders of Brittany and Poitou; but as regards north-western Europe it seems of late years to have bred only in Holland, and there it has been deprived by drainage of its favourite resorts, one after the other, so that it must shortly become merely a stranger, except in Spain or the basin of the Danube and other parts of south-eastern Europe.

The Spoonbill ranges over the greater part of middle and southern Asia,[2] and breeds abundantly in India, as well as on some of the islands in the Red Sea, and seems to be resident throughout Northern Africa. In Southern Africa its place is taken by an allied species with red legs, *P. cristata* or *tenuirostris*,

[1] Nothing shows better the futility of the old statutes for the protection of birds than the fact that in 1534 the taking of the eggs of Herons, Spoonbills (Shovelars), Cranes, Bitterns and Bustards was visited by a heavy penalty, while there was none for destroying the parent birds in the breeding season. All of the species just named, except the Heron, have passed away, while there is strong reason to think that some at least might have survived had the principle of the Levitical law (Deut. xxii. 6) been followed.

[2] Ornithologists have been in doubt as to the recognition of two species from Japan described by Temminck and Schlegel under the names of *P. major* and *P. minor*. It has been suggested that the former is only the young of *P. leucorodia*, and the latter the young of the Australian *P. regia*.

which also goes to Madagascar. Australia has two other species, *P. regia* or *melanorhynchus*, with black bill and feet, and *P. flavipes*, in which those parts are yellow. The very beautiful and wholly different *P. ajaja* is the Roseate Spoonbill of America, and is the only one found on that continent, the tropical or juxta-tropical parts of which it inhabits. The rich pink, deepening in some parts into crimson, of nearly all its plumage, together with the yellowish green of its bare head and its lake-coloured legs, sufficiently marks this bird; but all the other species are almost wholly clothed in pure white, though the English has, when adult, a fine buff pectoral band, and the spoon-shaped expanse of its bill is yellow, contrasting with the black of the compressed and basal portion. Its legs are also black. In the breeding season, a pendent tuft of white plumes further ornaments the head of both sexes, but is longest in the male. The young of the year have the primary quills dark-coloured.

The Spoonbills form a natural group, Plataleinae, allied to the Ibididae, and somewhat more distantly to the Storks (see STORK). They breed in societies, not only of their own kind, but in company with Herons, either on trees or in reed-beds, making large nests in which are commonly laid four eggs—white, speckled, streaked or blotched, but never very closely, with light red. Such breeding stations have been several times described, as for instance by P. L. Sclater and W. A. Forbes (*Ibis*, 1877, p. 412), and H. Seebohm (*Zoologist*, 1880, p. 457), while a view of another has been given by H. Schlegel (*Vög. Nederland*, taf. xvii.). (A. N.)

SPORADES (Gr. Σποράδες, from σπείρειν, to sow), the islands scattered about the Greek Archipelago, as distinguished from the Cyclades, which are grouped round Delos, and from the islands attached, as it were, to the mainlands of Europe and Asia. Ancient and modern writers differ as to the list of the Sporades (see Bursian, *Griechenland*, ii. 348 seq.). The Doric Sporades —Melos, Pholegandros, Sikinos, Thera, Anaphe, Astropalia and Cos—were by some considered a southern cluster of the Cyclades. In modern times the name Sporades is more especially applied to two groups—the northern Sporades, which lie north-east of Negropont (Euboea), Skiathos, Skopelos and Ikos being included in the department of Magnesia and Scyros in that of Euboea; and the southern Sporades, lying off the south-west of Asia Minor, being included in the Turkish vilayet of the "Islands of the White Sea." The northern, which have altogether an area of 180 sq. m. and a population of 12,250 (1896), comprise Skiathos (pop. 2790), Ikos (pop. 653), Skopelos (pop. 5295), Pelagonisi, Giura, Pipari and Scyros (pop. 3512), with the adjacent islets. Skiathos is a beautifully wooded and picturesque island; the town stands on a declivity surrounding an excellent harbour. The larger island of Skopelos is also well wooded. Almost every householder in both islands is the owner, joint owner or skipper of a sailing ship. The southern Sporades are as follows: Icaria, Patmos, Leros, Calymnus, Astropalia (Astypalaea or Stampalia), Cos (Stanko), Nisyros, Tilos or Episcopi, Syme, Khalki, Rhodes, Crete and many smaller isles. Icaria (pop. about 8000) derives its name from the legend of Icarus. The forests which it once possessed have been destroyed by the inhabitants for the manufacture of charcoal. Leros (pop. about 3000) was in ancient times a seat of the worship of Artemis. Calymnus (pop. about 7000) was once covered by forests—(Ovid, *A.A.* ii. 81, "silvis umbrosa Calymne"), which have disappeared. Nisyros (pop. about 2500) possesses hot sulphur springs.

SPOROZOA, a large and most important section of the Protozoa, all the members of which are exclusively parasitic in habitat. They are of extremely widespread occurrence; there is hardly one of the chief classes of animals which does not furnish hosts for these parasites, scarcely one of the common tissues or organs of the Metazoan body which may not be liable to infection. Sporozoa differ greatly as regards the effects which they produce upon their hosts. In many, perhaps in most, cases the general health of the infected animal seems to be unimpaired, even though the parasites may be fairly abundant. Some, however, give rise to dangerous or fatal diseases, while others may cause ravaging epidemics; instances of these are given under the various orders.

Correlated with the mode of life are the two features characteristic of all Sporozoa: (*a*) They absorb only fluid nutriment, osmotically, and so lack any organs for ingesting and digesting solid food; and (*b*) they reproduce by sporulation, *i.e.* the formation of minute germs, which are in most instances very numerous and are often enclosed in firm protective envelopes or cases, each case with its contents forming a *spore*. In addition, the great majority have also another method of reproduction, for increasing the number of the parasites in any individual host; this is distinguished as multiplicative or endogenous reproduction, from the propagative or exogenous method (by means of the resistant spores), which serves for the infection of fresh hosts and secures the dissemination and survival of the species. Further, most if not all forms of Sporozoa undergo sexual conjugation at some period or other of the life-cycle.

Beyond this, however, it is impossible to generalize. In response to the exceeding diversity of habitat and of the conditions of life, the parasites exhibit manifold and widely-different types of form, organization and life-history. The recognition of this fact is expressed, at the present day, by the division of the Sporozoa into several well-defined orders, which are grouped in two main divisions, each containing more or less closely related forms. One of these groups consists of the Gregarines, Coccidia and Haemosporidia (*qq.v.*). The other comprises the Myxosporidia, Actinomyxidia, Sarcosporidia and Haplosporidia, the parasites included in the last named order being of comparatively simple structure, and probably near the base of this section. There are, in addition, various other forms (Sero- and Exo-sporidia), also primitive in character, but which are as yet too insufficiently known for it to be certain whether they are of distinct ordinal rank, or should be placed with the Haplosporidia.

The nomenclature assigned to these two principal divisions of the Sporozoa by different writers has varied according to the particular character on which they have primarily based the arrangement. Of late years, the terms Telosporidia and Neosporidia, proposed by F. Schaudinn (1900), have been most in favour. In the Telosporidia (comprising the Gregarines, Coccidia and Haemosporidia), sporulation does not begin until the close of the vegetative or trophic period, *i.e.* until growth has ceased; in the Neosporidia (including the remaining orders) growth and sporulation go on coincidently. Recently, however, considerable doubt has been thrown upon the general occurrence of this latter condition in certain Myxosporidia (*Microsporidia*); and the present writer adopts as preferable, therefore, the terms *Ectospora* and *Endospora* (*qq.v.*), invented by E. Metschnikoff and made use of by F. Mesnil (1899), which indicate a universal distinction between the two groups in their manner of sporulation. This distinction is probably the most fundamental one, and itself supports a conclusion which is, on other grounds, becoming more and more likely, namely, that these two divisions are not related phylogenetically; but have, on the contrary, a radically different origin. In other words, under the heading Sporozoa, as at present used, are included two entirely independent series of Protozoan parasites; the general resemblances which these exhibit are due to convergence brought about by their specialized mode of life.

The most recent and comprehensive account of the group is that by E. A. Minchin (in Lankester's *Treatise on Zoology*, pt. i., London, 1903), to which the present writer is much indebted; another useful treatise is that of F. Doflein, *Die Protozoen als Parasiten u. Krankheitserreger* (G. Fischer, Jena, 1901). Earlier accounts are those of M. Lühe, *Ergebnisse der neuren Sporozoenforschung* (Jena, 1900); Wasielewski, *Sporozoenkunde* (Jena, 1896); Y. Delage and E. Hérouard in *Traité de zoologie concrète*, pt. i., Paris, 1896); E. R. Lankester, art. "Protozoa" in *Ency. Brit.* 9th ed. (1886), and O. Bütschli in Bronn's *Klassen u. Ordnungen des Thierreichs*, I. i. (1882). There is a systematic enumeration of the group by A. Labbé in *Das Thierreich*, 5. (Berlin, 1899); and the classification and phylogeny are considered by E. Mesnil (*Soc. Biol.*, vol. jub. p. 258, Paris, 1899), and by H. Crawley in *Amer. Nat.* (1905), xxxix. 607. (H. M. Wo.)

SPORRAN (Gaelic *sporan*, purse, pouch), a pouch which is worn, in Highland costume, hanging from the belt over the front of the kilt. The older sporrans were quite modest objects and ordinarily of leather; in modern Highland costume and in the uniform of Highland kilted regiments it has become a highly ornamental adjunct, with silver or metal rims, and a heavy long backing of horsehair or fur.

SPORT (a contracted or shortened form of "disport," to amuse, divert oneself, O. Fr. *se disporter* or *deporter*, to leave off work, hence to play, Lat. *dis-*, away, and *portare*, to carry; the origin of the meaning lies in the notion of turning away from serious occupations, cf. "diversion"), play, amusement, entertainment or recreation. The term was applied in early times to all forms of pastime. It was, however, particularly used of out-of-door or manly recreations, such as shooting with the bow, hunting and the like. Modern usage has given several meanings to "sport" and "sports." Generally speaking "sport" includes the out-of-door recreations, the "field-sports," such as fishing, shooting, fox-hunting, &c., connected with the killing or hunting of animals as opposed to organized "games," which are contests of skill or strength played according to rules. It also includes the special class of horse-racing, the votaries of which, and also of the prize-ring, have arrogated to themselves sometimes the name of "sportsman," applying that word even to those who follow racing simply as an occasion for betting. On the other hand, the plural "sports" is generally confined to athletic contests such as running, jumping, &c. (see ATHLETIC SPORTS and subsidiary articles).

In zoology and botany the word has a specific meaning of a sudden or singular variation from type, a "diversion" in a more etymological sense of the term.

SPORTS, THE BOOK OF, or more properly the DECLARATION OF SPORTS, an order issued by James I. in 1617 on the recommendation of Thomas Morton, bishop of Chester, for use in Lancashire, where the king on his return from Scotland found a conflict on the subject of Sunday amusements between the Puritans and the gentry, many of whom were Roman Catholics. Permission was given for dancing, archery, leaping, vaulting and other harmless recreations, and of "having of May games, Whitsun ales and morris dances, and the setting up of May-poles and other sports therewith used, so as the same may be had in due and convenient time without impediment or neglect of divine service, and that women shall have leave to carry rushes to church for the decorating of it." On the other hand, "bear and bull-baiting, interludes, and (at all times in the meane sort of people by law prohibited) bowling" were not to be permitted on Sunday (Wilkins, *Concilia*, iv. 483). In 1618 James transmitted orders to the clergy of the whole of England to read the declaration from the pulpit; but so strong was the opposition that he prudently withdrew his command (Wilson, in Kennet, ii. 709; Fuller, *Church History*, v. 452). In 1633 Charles I. not only directed the republication of his father's declaration (Rushworth, ii. 193) but insisted upon the reading of it by the clergy. Many of the clergy were punished for refusing to obey the injunction. With the fall of Laud all attempts to enforce it necessarily came to an end.

SPOTSWOOD (SPOTTSWOOD or SPOTTISWOOD), **ALEXANDER** (1676–1740), American colonial governor, was born, of an old Scotch family, in Tangier, Africa, in 1676. He served under Marlborough in the War of the Spanish Succession, and was wounded at Blenheim. He became lieutenant governor of Virginia in June 1710, when he was received with some enthusiasm, because he brought to the colony the privilege of *habeas corpus*; his term as governor closed in September 1722—probably because he meddled in ecclesiastical matters; but he remained in Virginia, living near his ironworks in Germanna, a settlement of Germans, on the Rapidan in Spottsylvania county (named in his honour) and he was deputy postmaster-general of the colonies from 1730 to 1739. He was the first representative of the British government in America who fully appreciated the value of the western territory. As governor he recommended the establishment of a Virginia company to carry on trade with the Indians, he urged upon the provincial government and also upon the British authorities the wisdom of constructing forts along the frontier, and he personally organized and conducted an exploring expedition (Aug. 17 to Sept. 20, 1716) into the Shenandoah Valley reaching the water-parting between the Atlantic and the Ohio river.[1] These ambitious and expensive schemes, coupled with his haughty and overbearing conduct, involved him in a controversy with the rather niggardly House of Burgesses. He developed the iron industry of Virginia, promoted the religious education of the Indians and tried to advance the interests of education, and especially of the College of William and Mary. In 1740 he was commissioned major-general to conduct the expedition against Cartagena, but died while attending to the embarcation, at Annapolis, Maryland, on the 7th of June 1740. His library he left to the College of William and Mary.

See R. A. Brock (ed.), "The Official Letters of Alexander Spotswood" (with a memoir), in *The Collections of the Virginia Historical Society* (2 vols., Richmond, 1882–1885).

SPOTTISWOODE (SPOTTISWOOD, SPOTISWOOD or SPOTSWOOD), **JOHN** (1565–1639), archbishop of St Andrews and historian of Scotland, eldest son of John Spottiswood, minister of Calder and "superintendent" of Lothian, was born in 1565. He was educated at Glasgow University (M.A. 1581), and succeeded his father in the parish of Calder in 1583. In 1601 he attended Ludowick, duke of Lennox, as his chaplain, in an embassy to the court of France, returning in 1603. He followed James to England on his accession, but was the same year nominated to the see of Glasgow, his consecration in London, however, not taking place until October 1610. Spottiswoode had originally become prominent as an ardent supporter of the strict Presbyterian party, but gradually came to see the inconveniences of "parity in the Church," attributed little importance to the existing matters of dispute, and thought that the interests of both church and state were best secured by keeping on good terms with the king. He was therefore ready to co-operate with James in curtailing the powers of the Kirk which encroached on the royal authority, and in assimilating the church of Scotland to that of England. On the 30th of May 1605 he became a member of the Scottish privy council. In 1610 he presided as moderator over the assembly in which presbytery was abolished, in 1615 he was made archbishop of St Andrews and primate of Scotland, and in 1618 procured the sanction of the privy council to the Five Articles of Perth with their ratification by parliament in 1621. In 1633 he crowned Charles I. at Holyrood. In 1635 he was appointed lord chancellor of Scotland, an office which he retained till 1638. He was opposed to the new liturgy as inexpedient, but when he could not prevent its introduction he took part in enforcing it. He was a spectator of the riot of St Giles's, Edinburgh, on the 23rd of July 1637, endeavoured in vain to avoid disaster by concessions, and on the taking of the Covenant perceived that "now all that we have been doing these thirty years past is thrown down at once." He escaped to Newcastle, was deposed by the assembly on the 4th of December on a variety of ridiculous charges, and died in London on the 26th of November 1639, receiving burial in Westminster Abbey. Spottiswoode published in 1620 *Refutatio libelli de regimine ecclesiae scoticanae*, an answer to a tract of Calderwood, who replied in the *Vindiciae* subjoined to his *Altare damascenum*, (1623). The only other writing published during his lifetime was the sermon he preached at the Perth assembly. His most considerable work was *The History of the Church and State of Scotland* (London, 1655, seq.). It displays considerable research and sagacity, and even when dealing with contemporary events gives a favourable impression, upon the whole, of the author's candour and truth. The opposite side can be studied in Calderwood's *History*.

Spottiswoode married Rachel, daughter of David Lindsay, bishop of Ross, and besides a daughter left two sons, Sir John Spottiswoode of Dairsie in Fife, and Sir Robert, president of

[1] To each of his comrades in this journey Spotswood presented a small golden horseshoe, lettered "Sic juvat transcendere montes."

the Court of Session, who was captured at the battle of Philiphaugh in 1645 and executed in 1646.

See the accounts prefixed to the first edition of Spottiswoode's *History of Scotland* and to that published by the Spottiswoode Society in 1851; also David Calderwood's *Hist. of the Kirk of Scotland* (1842–1849).

SPOTTISWOODE, WILLIAM (1825–1883), English mathematician and physicist, was born in London on the 11th of January 1825. His father, Andrew Spottiswoode, who was descended from an ancient Scottish family, represented Colchester in parliament for some years, and in 1831 became junior partner in the firm of Eyre & Spottiswoode, printers. William was educated at Laleham, Eton, Harrow and Balliol College, Oxford. His bent for science showed itself while he was still a schoolboy, and indeed his removal from Eton to Harrow is said to have been occasioned by an accidental explosion which occurred whilst he was performing an experiment for his own amusement. At Harrow he obtained in 1842 a Lyon scholarship, and at Oxford in 1845 a first-class in mathematics, in 1846 the junior and in 1847 the senior university mathematical scholarship. In 1846 he left Oxford to take his father's place in the business, in which he was engaged until his death. In 1847 he issued five pamphlets entitled *Meditationes analyticae*. This was his first publication of original mathematical work; and from this time scarcely a year passed in which he did not give to the world further mathematical researches. In 1856 Spottiswoode travelled in eastern Russia, and in 1860 in Croatia and Hungary; of the former expedition he has left an interesting record entitled *A Tarantasse Journey through Eastern Russia in the Autumn of 1856* (London, 1857). In 1870 he was elected president of the London Mathematical Society. In 1871 he began to turn his attention to experimental physics, his earlier researches bearing upon the polarization of light and his later work upon the electrical discharge in rarefied gases. He wrote a popular treatise upon the former subject for the "Nature" Series (1874). In 1878 he was elected president of the British Association, and in the same year president of the Royal Society, of which he had been a fellow since 1853. He died in London of typhoid fever on the 27th of June 1883, and was buried in Westminster Abbey.

As a mathematician he occupied himself with many branches of his favourite science, more especially with higher algebra, including the theory of determinants, with the general calculus of symbols, and with the application of analysis to geometry and mechanics. The following brief review of his mathematical work is quoted from the obituary notice which appeared in the *Proceedings of the Royal Society* (xxxviii. 34): "The interesting series of communications on the contact of curves and surfaces which are contained in the *Philosophical Transactions* of 1862 and subsequent years would alone account for the high rank he obtained as a mathematician. . . . The mastery which he had obtained over the mathematical symbols was so complete that he never shrank from the use of expressions, however complicated—nay, the more complicated they were the more he seemed to revel in them—provided they did not sin against the ruling spirit of all his work—symmetry. To a mind imbued with the love of mathematical symmetry the study of determinants had naturally every attraction. In 1851 Mr Spottiswoode published in the form of a pamphlet an account of some elementary theorems on the subject. This having fallen out of print, permission was sought by the editor of *Crelle* to reproduce it in the pages of that journal. Mr Spottiswoode granted the request and undertook to revise his work. The subject had, however, been so extensively developed in the interim that it proved necessary not merely to revise it but entirely to rewrite the work, which became a memoir of 116 pages. To this, the first elementary treatise on determinants, much of the rapid development of the subject is due. The effect of the study on Mr Spottiswoode's own methods was most pronounced; there is scarcely a page of his mathematical writings that does not bristle with determinants." His papers, numbering over 100, were published principally in the *Philosophical Transactions, Proceedings of the Royal Society, Quarterly Journal of Mathematics, Proceedings of the London Mathematical Society* and *Crelle*, and one or two in the *Comptes rendus* of the Paris Academy; a list of them, arranged according to the several journals in which they originally appeared, with short notes upon the less familiar memoirs, is given in *Nature*, xxvii. 599.

SPOTTSYLVANIA, a county of Virginia, U.S.A., so called after Alexander Spotswood (*q.v.*), lieutenant governor of Virginia in 1710–1722, who owned extensive estates and mines therein. It is bounded on the N. by the Rapidan and Rappahannock rivers and on the S. by the North Anna. It is celebrated as containing several of the most famous battlefields of the Civil War—Fredericksburg, Chancellorsville, the Wilderness, and particularly that of Spottsylvania Court House, where the armies of Grant and Lee contended for nearly two weeks (May 8-21, 1864). The battles of Chancellorsville, Wilderness and Spottsylvania are described in the article WILDERNESS.

SPOUSE, (O. Fr. *espous*, mod. *époux, espouse, épouse*, Lat. *sponsus, sponsa*, a betrothed or promised man or woman, from *spondere*, to promise), a husband or wife, properly one promised or betrothed to another in marriage.

SPRAT, THOMAS (1635–1713), English divine, was born at Beaminster, Dorsetshire, and educated at Wadham College, Oxford, where he held a fellowship (1657–1670). Having taken orders he became a prebendary of Lincoln in 1660. In the preceding year he had gained a reputation by his poem *To the Happie Memory of the most Renowned Prince Oliver, Lord Protector* (London, 1659), and he was afterwards well known as a wit, preacher and man of letters. His chief prose works are the *Observations upon Monsieur de Sorbier's Voyage into England* (London, 1665), a satirical reply to the strictures on Englishmen in Samuel de Sorbière's book of that name, and a *History* of the Royal Society of London (London, 1667), which Sprat had helped to found. In 1669 he became canon of Westminster, and in 1670 rector of Uffington, Lincolnshire. He was chaplain to Charles II. in 1676, curate and lecturer at St Margaret's, Westminster, in 1679, canon of Windsor in 1681, dean of Westminster in 1683 and bishop of Rochester in 1684. He was a member of James II.'s ecclesiastical commission, and in 1688 he read the Declaration of Indulgence to empty benches in Westminster Abbey. Although he opposed the motion of 1689 declaring the throne vacant, he assisted at the coronation of William and Mary. As dean of Westminster he directed Wren's restoration of the abbey. He died on the 20th of May 1713.

SPRAT, a marine fish (*Clupea sprattus*), named "garvie" in Scotland, one of the smallest species of the genus *Clupea* or herrings, rarely exceeds 5 in. in length, and occurs in large shoals on the Atlantic coasts of Europe. Sprats are very often confounded with young herrings, which they much resemble, but can always be distinguished by the following characters: they do not possess any teeth on the palate (vomer), like herrings; their gill-covers are smooth, without the radiating striae which are found in the shad and the pilchard; the anal fin consists of from seventeen to twenty rays, and the lateral line of forty-seven or forty-eight scales. The ventral fins are slightly anterior to the origin of the dorsal fin; and the spine consists of from forty-seven to forty-nine vertebrae. The sprat spawns in the open sea from February to May and is only occasionally captured in the ripe condition. Its eggs are buoyant and pelagic and easily recognized. The sprat is one of the more important food-fishes on account of the immense numbers which are caught when the shoals approach the coasts. They are somewhat capricious, however, as regards the place and time of their appearance, the latter falling chiefly in the first half of winter. They are caught with the seine or with the bag-net in the tideway. Large quantities are consumed fresh, but many are pickled or smoked and others prepared like anchovies. Frequently the captures are so large that the fish can be used as manure only.

SPRATT, THOMAS ABEL BRIMAGE (1811–1888), English vice-admiral, hydrographer and geologist, was born at East Teignmouth on the 11th of May 1811. He was the eldest son of Commander James Spratt, R.N., and entered the navy in 1827. He was attached to the surveying branch, and was engaged almost continuously until 1863 in surveying the Mediterranean. As commander of the "Spitfire" he rendered distinguished service in the Black Sea during the Crimean War, and was appointed C.B. in 1855. At an earlier date he was associated with Edward Forbes, then naturalist to the "Beacon," and during the years 1841–1843 they made observations on the bathymetrical distribution of marine life. To Forbes he was specially indebted for his interest in natural history and geology, and together they published *Travels in Lycia, &c.* (1847). Spratt investigated the caves at Malta and obtained remains of the pigmy elephant (*Elephas melitensis*), which was described by Dr H. Falconer. He investigated the geology of several Greek islands, also the shores of Asia Minor, and made detailed observations on the Delta of the Nile. He was especially distinguished for his *Travels and Researches in Crete* (2 vols., 1865), in which he ably described the physical geography, geology, archaeology and natural history of the island. He was commissioner of fisheries from 1866 to 1873; and acting conservator of the Mersey from 1879 until the close of his life. He died at Tunbridge Wells on the 10th of March 1888.

SPRECKELS, CLAUS (1828–1908), American capitalist, was born in Lanstedt, Hanover, in 1828. In 1846, to escape army service, he emigrated to the United States and became a grocer. In 1856 he removed from New York City to San Francisco, where he set up as a grocer, then a brewer, and later a sugar refiner. He gradually obtained control of most of the sugar refineries on the Pacific coast; he was able to undersell his competitors because he bought his raw sugar in Hawaii, where he purchased large plantations and contracted for the produce of others. He built a large refinery in Hawaii, and his influence with the Hawaiian government was for a time paramount. By financing the Pacific Steamship Company he was able to reduce the freight charges on his sugar, and he also introduced various improvements in the methods of manufacture. It was he who built the railway from Salinas to San Francisco, by buying which the Atchison, Topeka & Santa Fé first made a through line into San Francisco. Spreckels died in San Francisco on the 26th of December 1908. His eldest son, John Diedrich Spreckels (b. 1853), became proprietor of the *San Francisco Morning Call* and succeeded to his father's steamship interests; and another son, Rudolph Spreckels (1873–), became president of the First National Bank of San Francisco.

SPREE, a river of Prussia, Germany, rising in the district of Upper Lusatia, in the kingdom of Saxony, close to the Bohemian frontier, and flowing nearly due north past Bautzen, Spremberg and Cottbus, dividing between the first two towns for a time into two arms. Below Cottbus the river splits into a network of channels, and swings round in a big curve to the west forming the peculiar marshy region (30 m. long and 3 to 6 m. wide) known as the Spreewald. Having returned to its predominant direction, it turns W.N.W., and passing Fürstenwalde and Köpenick threads Berlin in several arms, and joins the Havel at Spandau. Its length is 227 m. of which 112 are navigable; the area of its drainage basin is 3660 sq. m. It is connected with the Oder by the Friedrich Wilhelm or Müllrose Canal made in 1862–1868, which is 17 m. long, and by the Oder-Spree Canal, made in 1887–1888, and with the Havel by the Berlin-Spandau Navigation Canal, 5½ m. long, and by the Teltow Canal completed in 1905.

SPREEWALD, a district of Germany, in the Prussian province of Brandenburg, a marshy depression of the middle Spree valley, extending to some 106 sq. m., its length being 27 m. and its width varying from 1 to 7 m. It owes its marshy character to the river Spree, which above Lübben splits into a network of over two hundred arms, and in seasons of flood generally overflows considerable portions of the region. In the parts which are especially liable to inundation, as, for example, the villages of Lehde, Leipe and Burg, many of the homesteads are built each on a little self-contained island, approachable in summer only by boat, and in winter over the ice. In spite of its marshy character the Spreewald is in part cultivated, in part converted into pasturage, and almost everywhere, but more especially in the lower districts, wooded like a park, the predominant trees being willows. Fishing, cattle-breeding and the growing of vegetables, more particularly small pickling cucumbers, are the chief occupations of the people, about 30,000 in all. In great part they are of Wendish blood, and though the majority have been Germanized, there is a small residue who have faithfully preserved their national speech, customs, and their own peculiar styles of dress. The attractive blending of wood and water makes the Spreewald in summer a resort of the people of the Prussian capital, but also in winter the district is largely visited by people bent on skating, sleighing and other winter pastimes. The chief town is Lübben, 45 m. south from Berlin on the railway to Görlitz.

See W. von Schulenburg, *Wendische Volkssagen und Gebräuche aus dem Spreewald* (Leipzig, 1880); Kühn, *Der Spreewald und seine Bewohner* (Cottbus, 1889); and Braunsdorf, *Spreewaldfahrten* (Lübbenau, 1901).

SPREMBERG, a town of Germany, in the Prussian province of Brandenburg, situated partly on an island in the river Spree and partly on the west bank, 76 m. S.E. of Berlin by the railway to Görlitz. Pop. (1905) 11,188. There are a Roman Catholic and two Evangelical churches, a pilgrimage chapel, dating from 1100, a ducal château, built by a son of the elector John George about the end of the 16th century (now utilized as government offices), classical, technical and commercial schools and a hospital. It carries on considerable manufactures of woollen cloth.

SPRENGEL, KURT (1766–1833), German botanist and physician, was born on the 3rd of August 1766 at Bodelkow in Pomerania. His uncle, Christian Konrad Sprengel (1750–1816), is remembered for his studies in the fertilization of flowers by insects—a subject in which he reached conclusions many years ahead of his time. His father, a clergyman, provided him with a thorough education of wide scope; and the boy at an early age distinguished himself as a linguist, not only in Latin and Greek, but also in Arabic. He appeared as an author at the age of fourteen, publishing a small work called *Anleitung zur Botanik für Frauenzimmer* in 1780. In 1784 he began to study theology and medicine at the university of Halle, but soon relinquished the former. He graduated in medicine in 1787. In 1789 he was appointed extraordinary professor of medicine in his *alma mater*, and in 1795 was promoted to be ordinary professor. He devoted much of his time to medical work and to investigations into the history of medicine; and he held a foremost rank as an original investigator both in medicine and botany. Among the more important of his many services to the latter science was the part he took in awakening and stimulating microscopic investigation into the anatomy of the tissues of the higher plants, though defective microscopic appliances rendered the conclusions arrived at by himself untrustworthy. He also made many improvements in the details of both the Linnaean and the "natural" systems of classification. He died of an apoplectic seizure at Halle on the 15th of March 1833.

Sprengel's more important works were: *Beiträge zur Geschichte des Pulses* (1787); *Galens Fieberlehre* (1788); *Apologie des Hippokrates* (1789); *Versuch einer pragmatischen Geschichte der Arzneikunde* (1792–1799); *Handbuch der Pathologie* (1795–1797); *Institutiones medicae* (6 vols., 1809–1816); *Geschichte der Medicin* (completed in 1820); *Antiquitatum botanicarum specimen* (1798); *Historia rei herbariae* (1807–1808); *Anleitung zur Kenntniss der Gewächse* (1802–1804; and again 1817–1818); *Geschichte der Botanik* (1817–1818); *Von dem Bau und der Natur der Gewächse* (1812); *Flora halensis* (1806–1815; and in 1832); *Species umbelliferarum minus cognitae* (1818); *Neue Entdeckung im ganzen Umfang der Pflanzenkunde* (1820–1822). He edited an edition of Linnaeus's *Systema vegetabilium* in 1824 and of the *Genera plantarum* in 1830. A list of his botanical papers from 1798 onwards will be found in the Royal Society's *Catalogue of Scientific Papers*.

SPRENGER, JAKOB (*fl.* 1500), the Dominican inquisitor of Cologne, who with Heinrich Krämer (institor) published *Malleus maleficarum* or *Hexenhammer*, the standard textbook on witchcraft, especially in Germany. The book gives (1) evidences of witchcraft; (2) rules for discovering it; (3) proceedings for punishment.

SPRENGTPORTEN, GÖRAN MAGNUS, Count (1740–1819), Swedish and Russian politician, younger brother of Jakob Magnus Sprengtporten, entered the army and rose to the rank of captain during the Seven Years' War. He assisted his brother in the revolution of 1772, and in 1775 was made a colonel and brigadier in east Finland. Here he distinguished himself greatly as an organizer and administrator. The military school which he founded at Brahelinnd subsequently became a state institution. Irritable and suspicious like his brother he also came to the conclusion that his services had not been adequately appreciated, and the flattering way in which he was welcomed by the Russian court during a visit to St Petersburg in 1779 still further incensed him against the purely imaginary ingratitude of his own sovereign. For the next two years he was in the French service, returning to Finland in 1781. It was now that he first conceived the plan of separating the grand duchy from Sweden and erecting it into an independent state under the protection of Russia. During the *riksdag* of 1786 he openly opposed Gustavus III., at the same time engaging in a secret and treasonable correspondence with the Russian ministers with the view of inducing them to assist the Finns by force of arms. In the following year, at the invitation of Catherine II., he formally entered the Russian service. When the Russo-Swedish War of 1788–90 began, Sprengtporten received the command of a Russian army corps directed against Finland. He took no direct part in the Anjala conspiracy (see SWEDEN: *History*), but urged Catherine to support it more energetically. His own negotiations with his fellow countrymen, especially after Gustavus III. had brought the Finlanders back to their allegiance, failed utterly. Nor was he able to serve Russia very effectively in the field for he was seriously wounded at the battle of Parosalmi (1790). At the end of the war, indeed, his position was somewhat precarious, as the High Court of Finland condemned him as a traitor, while Catherine regarded him as an incompetent impostor who could not perform his promises. For the next five years, therefore (1793–1798), he thought it expedient to quit Russia and live at Töplitz in Bohemia. He was re-employed by the emperor Paul who, in 1800, sent him to negotiate with Napoleon concerning the Maltese Order and the interchange of prisoners. After Paul's death Sprengtporten was again in disgrace for seven years, but was consulted in 1808 on the eve of the outbreak of hostilities with France. On the 1st of December 1808 he was appointed the first Russian governor-general of Finland with the title of count, but was so unpopular that he had to resign his post the following year. The last ten years of his life were lived in retirement.

See *Finska Tidskrift* (Helsingfors, 1877–1889); and *Svenska Letteratursällskapets i Finland förhandlingar* (Helsingfors, 1887). (R. N. B.)

SPRENGTPORTEN, JAKOB MAGNUS (1727–1786), Swedish soldier and politician. In his twelfth year he chose the profession of arms, and served his country with distinction. The few and miserable triumphs of Sweden during the Seven Years' War were due almost entirely to young Sprengtporten, and he emerged from it with a lieutenant-colonelcy, a pension of £20, and the reputation of being the smartest officer in the service. Sprengtporten, above all things a man of action, had too hearty a contempt for "Hats" and "Caps" to belong to either. He regarded the monstrous system of misrule for which they were primarily responsible with indignation, made no secret of his sentiments, and soon gathered round him a band of young officers of strong royalist proclivities, whom he formed into a club, the so-called *Svenska Botten* (Sweden's groundwork). The club was suppressed by the dominant "Caps," who also sought to ruin Sprengtporten financially by inciting his tenants in Finland to bring actions against him for alleged extortion, not in the ordinary courts but in the *riksdag* itself, where Sprengtporten's political adversaries would be his judges. The enraged Finnish colonel thereupon approached Gustavus III. with the project of a revolution against their common enemies, the "Caps." It was to begin in Finland where Sprengtporten's regiment, the Nyland dragoons, was stationed. He undertook to seize the impregnable fortress of Sveaborg by a *coup de main*. The submission of the whole grand duchy would be the natural consequence of such a success, and, Finland once secured, Sprengtporten proposed at the head of his Finns to embark for Sweden, meet the king and his friends near Stockholm, and surprise the capital by a night attack. This plan, subsequently enlarged by a suggestion of a fellow plotter, J. K. Toll (*q.v.*), was warmly approved of by the king. On the 22nd of July 1772 Sprengtporten left Stockholm. On the 9th of August he reached Helsingfors. On the 16th he persuaded the fortress of Sveaborg to submit to him. Helsingfors followed the example of Sveaborg. A week later all Finland lay at the feet of the intrepid colonel of the Borgå dragoons. By the 23rd of August Sprengtporten was ready to re-embark for Stockholm with 780 men, but contrary winds kept him back, and in the meantime Gustavus III. himself had carried out his revolution unaided. On his return to Sweden, however, Sprengtporten was received with the greatest distinction and made a lieutenant-general and colonel of the guards. He was also appointed the president of a commission for strengthening the defences of Finland. But Sprengtporten was still dissatisfied. He could never forgive Gustavus for having forestalled the revolution, and his morbidly irritable and suspicious temper saw slights and insults in the most innocent conjunctures. His first quarrel with Gustavus happened in 1774 when he refused to accept the post of commander-in-chief in Finland on the eve of threatened war with Russia. The king good-naturedly overlooked his outrageous insolence on this occasion, but the inevitable rupture was only postponed. A most trumpery affair brought matters to a head. Sprengtporten had insulted the guards by giving precedence over them at a court-martial to some officers of his own dragoons. The guards complained to the king, who, after consulting with the senate, mildly remonstrated with Sprengtporten by letter. Sprengtporten thereupon tendered his resignation as colonel of the guard, and at a personal interview with Gustavus was so violent and insolent that anything like agreement between them became impossible. Sprengtporten was haunted by the fixed idea that the *jeunesse dorée* of the court was in league with his old enemies to traduce and supplant him, and not all the forbearance of the king could open his eyes. He received a pension of £2400 a year on his retirement and was allowed the extraordinary privilege of a guard of honour as long as he lived. Nevertheless, to the end of his career, he continued to harass and annoy his long-suffering benefactor with fresh impertinences.

See R. N. Bain, *Gustavus III. and his Contemporaries*, vol. i. (London, 1895); C. Julin, *Gustavus III. och J. M. Sprengtporten*, *sv. Hist. Tid.* (Stockholm, 1903). (R. N. B.)

SPRING (from "to spring," "to leap or jump up," "burst out," O. Eng., *springan*, a common Teut. word, cf. Ger. *springen*, possibly allied to Gr. *σπέρχεσθαι*, to move rapidly), primarily the act of springing or leaping. The word is hence applied in various senses: to the season of the year in which plant life begins to bud and shoot; to a source of water springing or welling up from below the surface of the earth and flowing away as a stream or standing in a pool (see WATER SUPPLY); or to an elastic or resilient body or contrivance for receiving and imparting mechanical power. The most common form in which springs in this last sense are made is that of a spiral coil of wire or narrow band of steel. There are many uses to which they are put, *e.g.* for communicating motion, as in a clock or watch (*qq.v.*), or for relieving concussion, as in the case of carriages (*q.v.*).

SPRINGBUCK, or SPRINGBOK (*Antidorcas euchore*), an aberrant South African gazelle inhabiting the country south of the Zambezi, but ranging north-westwards to Mossamedes. In the more settled parts of Cape Colony, the Transvaal and the Orange Free State it now only exists within the enclosures of the large farms, and can hardly be said to be any longer truly wild. Both sexes carry lyrate horns; the shoulder-height of an adult male is about 30 in., and an average pair of horns measures 14 in. along the curve; in the female the horns are more slender. The general colour above is reddish fawn, separated from the white of the under-parts by a dark band on the flanks. Along the middle of the hinder half of the back is a line of long erectile white hairs, forming the "fan," continued down over the rump; in repose this is concealed by the surrounding hair, but is conspicuously displayed when the animal takes the great leaps from which it derives its popular name. The periodical migrations of springbuck are well known, and though the *treks* are small compared with those of about 1850, they still include very large herds. In 1896 there was a great *trek*, and about then in the north of Cape Colony a herd was seen which was estimated at 500,000 head.

SPRINGER, ANTON HEINRICH (1825–1891), German writer, was born at Prague on the 13th of July 1825 and was educated at the university of his native city. Taking an interest in art, he visited Munich, Dresden and Berlin, and spent some months in Italy; afterwards he settled at Tübingen and in 1848 he returned to Prague and began to lecture at his own university on the history of the revolutionary epoch. The liberal tone of these lectures brought him into disfavour with the ruling authorities, and in 1849 he left Bohemia and passed some time in England, France and the Netherlands. In 1852 he settled at Bonn, where he lectured on art and became a professor in 1859; in 1872 he went to the university of Strassburg and in 1873 to Leipzig. As a journalist and a publicist Springer advocated the federal union of the states ruled by the Austrian emperor, and asserted the right of Prussia to the headship of Germany; during the Crimean War he favoured the emancipation of the small states in the south-east of Europe from Turkish supremacy. After many years of feeble health, he died at Leipzig on the 31st of May 1891.

Springer is known as a writer both on history and on art. In the former connexion his most important work is his *Geschichte Oesterreichs seit dem wiener Frieden* (Leipzig, 1863–1865), which has been translated into Czech (Prague, 1867). His other historical works are: *Geschichte des Revolutionszeitalters* (Prague, 1849); *Oesterreich nach der Revolution* (Prague, 1850); *Oesterreich, Preussen und Deutschland* (Prague, 1851); *Paris im xiii. Jahrhundert* (Leipzig, 1856); and *Protokolle des Verfassungs-Ausschusses im oesterreichischen Reichstage 1848–1849* (Leipzig, 1885). His principal works on art are: *Baukunst des christlichen Mittelalters* (Bonn, 1854); the valuable *Handbuch der Kunstgeschichte* (7th ed., Leipzig, 1906), a revised edition of his *Grundzüge der Kunstgeschichte* (Leipzig, 1887–1888); *Geschichte der bildenden Künste im xix. Jahrhundert* (Leipzig, 1858); *Bilder aus der neueren Kunstgeschichte* (Bonn 1867, and again 1886); *Raffael und Michelangelo* (Leipzig, 1877 and 1885); and *Die Kunst des xix. Jahrhunderts* (Leipzig 1880–1881). Springer wrote two biographies: *Friedrich Christoph Dahlmann* (Leipzig, 1870–1872), and *Albrecht Dürer* (Berlin, 1892); and was responsible for the German edition of Crowe and Cavalcaselle's *Lives of the Early Flemish Painters*, which was published at Leipzig in 1875. His book of reminiscences, *Aus meinem Leben* (Berlin, 1892), containing contributions by G. Freytag and H. Janitschek, was edited by his son Jaro Springer (b. 1856), who is also known as a writer on art.

SPRINGER (Fr. *rein*), the term given in architecture to the stone from which an arch springs (see ARCH); in some cases this is the stone resting on the impost or capital, the upper surface of which is a plane directed to the centre of the arch. In vaulting, however, where the lower stone of the arch or rib is laid in horizontal courses, so as to bond it well into the wall, constituting a system of construction known in France as the *tas-de-charge*, the springer may be considerably higher. The term is sometimes applied to the lowest stone of a gable.

SPRINGFIELD, the capital of Illinois, U.S.A., and the county-seat of Sangamon county, on the Sangamon river, in the central part of the state. Pop. (1890), 24,963; (1900), 34,159, of whom 4654 were foreign-born (1940 Germans, 1106 Irish and 499 English) and 2227 negroes; (1910 census) 51,678. Land area (1906), 7·07 sq. m., of which 3·37 sq. m. had been annexed since 1890. It is served by the Baltimore & Ohio South-Western, the Chicago & Alton, the Chicago, Peoria & St Louis, the Illinois Central, the Wabash, and the Cincinnati, Hamilton & Dayton railways, and by inter-urban electric lines. The city has a park and a boulevard system; the principal parks are Washington, Lincoln, Reservoir and Mildred. The chief public building is the state capitol (built in 1868–1888 at a cost of about $4,500,000), in the form of a Greek cross, with porticoes of granite and a dome 361 ft. high. It is the fifth state capitol of Illinois and the second erected in Springfield. Other prominent buildings are the Supreme Court building, the county court house (the old state capitol, finished in 1853), the city-hall, the state arsenal, the high school and the public library. In Oak Ridge cemetery, adjacent to the city, is the Lincoln monument, erected over Abraham Lincoln's grave with funds raised throughout the country by a Lincoln Monument Association. It was designed by Larkin G. Mead, and consists of a granite obelisk 121 ft. above the centre of a mausoleum, which is 119½ ft. long and 72½ ft. wide, and in which there are six crypts for the burial of members of Lincoln's family, and a memorial hall, a museum of Lincolniana. Around the foot of the obelisk (besides an heroic statue of Lincoln) are four groups of figures in bronze, symbolizing the army and navy of the United States. The monument was completed and dedicated in 1874, was transferred to the state in 1895, and restored and in large part rebuilt in 1899–1901. Lincoln's home (erected in 1839 and bought by Lincoln in 1844) in Springfield is well preserved by the state. In the city are the state library (1842), the state law library (1839), the Illinois historical library (1889), of which the State Historical Society (1903) is a department, and the Illinois Supreme Court library; several educational institutions, including Concordia-Seminar (Evangelical Lutheran), the Ursuline Academy (Roman Catholic), and the Academy of the Sacred Heart (Roman Catholic); the Springfield hospital (1897; Lutheran), and the St John's hospital (1875; under the Sisters of St Francis), two orphanages, two homes for aged women, and a sanatorium; the permanent grounds of the State Fair (157 acres), and a state rifle range and militia camp-ground (160 acres). Springfield is a trading and shipping centre for a prosperous agricultural region, and ships large quantities of bituminous coal from the immediate vicinity. The Wabash and the Chicago, Peoria & St Louis railways have large repair shops here. Among the manufactures are agricultural implements, watches and watch material—the Illinois Watch Company has a large factory here—lumber, flour, foundry and machine-shop products, automobiles, shoes and boilers. The total value of the factory product in 1905 was $5,976,637 (67·2 % more than in 1900). The first settlement was made in 1818. In 1821 the place was chosen to be the county-seat of the newly created Sangamon county and was named Springfield. In 1823 it was platted, and was named Calhoun in honour of John C. Calhoun, but this name was not popular and the former name was soon restored. Springfield was incorporated as a town in 1832 and chartered as a city in 1840. In 1837 the state legislature passed a bill making Springfield the capital, and in December 1839 the legislature first met here.

SPRINGFIELD, a city and the county-seat of Hampden county, Massachusetts, U.S.A., about 99 m. W. by S. of Boston and 26 m. N. of Hartford, Connecticut, on the east bank of the Connecticut river. Pop. (1800), 2312; (1850), 11,766; (1890), 44,179; (1900), 62,059, of whom 14,381 were foreign-born (5462 Irish, 2474 French Canadians, 1144 English-Canadians, 1321 English), 33,710 were of foreign parentage (either parent foreign-born), and 1021 were negroes; (1910, census), 88,926. Springfield is served by the Springfield division of the New York & New England, the Hartford division of the New York, New Haven & Hartford, the Connecticut River division of the Boston & Maine, and the Athol division and the main line of the Boston & Albany railways, and by inter-urban electric railway lines. The river is crossed here by four large bridges. The area of the city, which until 1852 was a township, is 38·53 sq. m. In its extreme eastern part is the small village of Sixteen Acres; north-west of the main part of the city on the Connecticut river is another village, Brightwood (on the Boston & Maine railway) and on the Chicopee river, north-east of the business part of the city, is the village of Indian Orchard, served by the Athol division of the Boston & Albany railway.

The city contains many public and private buildings of architectural importance. Among these are some of the earlier works of H. H. Richardson, such as the Court House, the Union railway station (1889), the Church of the Unity on State Street, and the North Congregational Church. Among other buildings are: Christ Church (Protestant Episcopal) St Michael's Cathedral (Roman Catholic), the South Congregational Church, the Memorial Church, and the Church of the Sacred Heart; the Art Museum (1894–1896), which contains the George Walter Vincent Smith art collection and an art library; the Horace

Smith Hall of Sculpture; the Museum of Natural History (1898), organized in 1859; a group of municipal buildings, with a tower 270 ft. high and a large auditorium; a government building (1891) containing the post office and custom house, the Hampden County Hall of Records, the City Library with 175,000 volumes, and two branch libraries given by Andrew Carnegie; a state armoury, and the business buildings of the Springfield Fire & Marine Insurance Company, the Union Trust Company, and the Institution for Savings. The Public Library, the Art Museum, and the Museum of Natural History are controlled by the City Library Association, organized in 1857. In the city are a government arsenal and armoury. The arsenal was established by the Continental Congress during the War of Independence and began to be used as a repository for arms and ammunition about 1777. The armoury, in the midst of a park on Armory Hill immediately east of the railway station, was established in 1794. Here the famous Springfield muskets used by the Federal forces during the Civil War were manufactured (800,000 having been made during that struggle) and it is still the principal manufactory of small arms for the United States army. Springfield has a good system of parks (under a board of park commissioners) with a total acreage of 550 acres. Forest Park (464 acres), in the southern part of the city, is the largest and most attractive; it contains a good zoölogical collection, and in its ponds is one of the finest collections in America of lotus plants and Oriental aquatic flora; at its southern entrance is a monument to President McKinley by Philip Martiny. In Merrick Park, adjoining the City Library, there is St Gaudens's famous statue of "The Puritan," commemorative of Deacon Samuel Chapin, one of the early settlers of the city. In Court Square are a statue of Miles Morgan (1616–1699), an early settler, by J. S. Hartley, and a monument in memory of the soldiers and sailors of the Civil War. In Carew Triangle in the northern part of the city is a monument in honour of soldiers of the Spanish-American War. In the suburbs of the city is Hampden Park, once a famous race track. There are two large cemeteries, in one of which are buried many of Springfield's famous men, including Samuel Bowles and J. G. Holland, whose grave is marked by a medallion by St Gaudens. Among the hospitals are the Mercy Hospital (1896, under the Sisters of Divine Providence), the Wesson Memorial (formerly Hampden Homeopathic) Hospital (1900), the Wesson Maternity Hospital (1906), and the Springfield Hospital (1883). The Springfield public school system is excellent, and in addition to the regular high school there are a technical high school, a vocational school, and a kindergarten training school. Other schools in Springfield are: the training school of the International Young Men's Christian Association (1885); the American International College, established in Lowell (1885) as the French-American College for the education of French-Canadians, and now working among various immigrant races; and the MacDuffie school (1890) and the Elms (1866), both schools for girls.

Springfield is noted for the diversity of its industries. In 1905 the capital invested in manufacturing establishments was $24,081,099, and in the value of its factory products ($25,860,250, not including those of the U.S. Arsenal; 42·4% more than in 1900) Springfield ranked ninth among the cities of Massachusetts. The largest single item in point of value was the product ($3,053,008) of the slaughtering and meat-packing establishments. Other important products were foundry and machine-shop products ($1,749,054); paper goods ($1,481,427, not including envelopes, which had an additional value of almost $700,000); cars, automobiles, firearms (besides the Federal arsenal there is the Smith & Wesson revolver factory); and printing and publishing ($1,165,544).

The principal newspapers are the *Springfield Republican* (Independent; weekly, 1824; morning, 1844), one of the most able and influential journals in New England, which since its establishment by Samuel Bowles (*q.v.*) has been the property of the Bowles family; the *Union* (Republican; morning, evening, and weekly; 1864); the *Daily News* (Democratic; 1880); and the *Springfield Homestead* (tri-weekly; 1878). The *New England Homestead* (weekly; published by the Orange Judd Company), *Farm and Home*, a semi-monthly, and *Good Housekeeping*, a monthly (published by the Phelps Publishing Company), and the *Kindergarten Review* (monthly, published by the Milton-Bradley Company, who publish other educational matter) are important periodicals.

The city is governed by a mayor, a board of aldermen (one from each of eight wards) and a common council of eighteen members (two or three from each ward, according to population), elected in December every other year. The city owns and operates the waterworks.

Springfield was founded in 1636 by a company of settlers from Roxbury led by William Pynchon (1590–1662). Pynchon, who had been one of the original patentees of the Massachusetts Bay Colony, was dissatisfied with the government of Roxbury, of which he had been a founder. On a trip to the Connecticut Valley he selected a spot for a new colony which should have a limited membership and in which his ideas as to government might be put into execution. Accompanied by a dozen families he removed thither early in 1636. The settlers found there a settlement of Agawam Indians (probably allied with the Pacomtuc), and the settlement was at first known as Agawam. For some time the political affiliation was with the Connecticut river towns in Connecticut, but later the authority of the Massachusetts General Court was recognized. In 1640 the name was changed to Springfield, after the native place of William Pynchon in Essex, England. For several years Pynchon was the dominating influence in the colony, ruling it with the power of an autocrat. In 1650 he published a tract (*The Meritorious Price of Our Redemption*) in which he attacked the Calvinistic doctrine of the atonement, and which was burned on Boston Common by order of the General Court. He was removed from the magistracy and returned to England in 1652. In King Philip's War Springfield was a centre of hostilities. In October 1675 a force of hostile Indians, joined by the hitherto friendly Agawams, surprised the settlers, killed some of them, drove the others into the three fortified houses, and burned the remaining buildings. They were preparing to storm the fortified houses when they were in turn attacked and driven off by a force of militia. Springfield was somewhat out of the track of operations of the warfare between the French and English in America, as it was later in the War of Independence; but men from Springfield served in all these conflicts. In 1777 the armoury was established and the place became an important military supply dépôt for the Continental forces. In July of that year representatives of the New England States and New York met here in convention to consider plans of co-operation for meeting Burgoyne's invasion. During Shays's rebellion there was a riot here in September 1786, and on the 25th of January 1787 the insurgent forces under Daniel Shays attacked the arsenal, but were dispersed by the militia under Brigadier-General William Shepard (1737–1817). Springfield remained little more than a large country market town until the completion of the Boston & Albany railway in 1839. From that time its growth as a railway and manufacturing centre was marked. Springfield was a strong abolition centre before the Civil War, and from here active plans were put in operation for sending material aid in the form of men and arms to the "free state" party in Kansas. The city was chartered in 1852.

See H. M. Burt, *First Century of the History of Springfield* (2 vols., Springfield, 1898–1899); J. E. Tower (ed.), *Springfield, Present and Prospective* (ibid., 1905); M. A. Green, *Springfield, 1636–1886* (ibid., 1888); Moses King, *Handbook of Springfield* (ibid., 1884).

SPRINGFIELD, a city and the county-seat of Greene county, Missouri, U.S.A., in the S.W. part of the state, about 238 m. from St Louis. Pop. (1890), 21,850; (1900), 23,267, of whom 2268 were negroes and 1057 foreign-born; (1910, census), 35,201. It is served by the St Louis & San Francisco, the Missouri Pacific, and the Kansas City, Clinton & Springfield railways. The city is pleasantly situated on the Ozark Dome, about 1300 ft. above sea-level, is regularly laid out on an undulating site, and has attractive residential districts. The principal building is that of the Federal government (1894), which is built of Indiana cut stone. Springfield is the seat of Loretto Academy, of a state normal school, and of Drury College (co-educational; founded in 1873 by Congregationalists, but now undenominational), which comprises, besides the college proper, an academy, a conservatory of music and a summer school, and which in 1908–1909 had 500 students. Near the city is the Academy of the Visitation under the Sisters of St Chantal. The municipal water-supply is drawn from springs 3 m. north of the centre of the city. There are four large private parks (340 acres) on the outskirts, and two municipal cemeteries—a Confederate cemetery, maintained by associations, the only distinctively Confederate burial ground in Missouri; and a National cemetery, maintained by the United States government. Springfield is one of the two chief commercial centres of this region, which has large mining, fruit, grain, lumber and livestock interests. The jobbing trade is important. Springfield ranks fourth among the manufacturing cities of the state; in 1905 the value of its factory products was $5,293,315 (28·2% more than in 1900). Flour and grist mill products constituted in 1905 a third of the total; and carriages and wagons ranked next. The St Louis & San Francisco railway has large shops here.

Springfield was settled in the years following 1829, and was laid out in 1833, though the public lands did not pass from the United States for sale until 1837. In 1838 and again in 1846 Springfield was incorporated as a town, and in 1847 was chartered as a city; though government lapsed during much of the time up to 1865, when prosperous conditions became settled. At the opening of the Civil War, Springfield was one of the most important strategic points west of the Mississippi river. In 1861–62 it was occupied or controlled a half dozen times in succession by the Confederate and the Union forces, the latter retaining control of it after the spring of 1862. In the battle of Wilson's Creek (August 10, 1861), fought about 10 m. south of the city, and one of the bloodiest battles of the war, relatively to numbers engaged, a force of about 5500 Union soldiers under General Nathaniel Lyon was defeated by about 10,000 Confederates under Generals Benjamin McCulloch (1811–1862) and Sterling Price. The other occupations and abandonments were unattended by serious conflicts in the immediate vicinity. In January 1863, after Springfield had been made an important Union supply post, it was attacked without success by a Confederate force of about 2000 men under General J. S. Marmaduke. The year 1870 was marked by the arrival of the first railway. In the same year North Springfield was laid out, and was incorporated as a town in 1870 and 1871. In 1881 Springfield was chartered as a city of a higher class, and in 1887 it absorbed North Springfield. After 1902 the city's growth in population and in industries was very rapid.

SPRINGFIELD, a city and the county-seat of Clark county, Ohio, U.S.A., at the confluence of Mad river and Lagonda Creek, about 45 m. W.S.W. of Columbus. Pop. (1890), 31,895; (1900), 38,253, of whom 3311 were foreign-born (including 1337 German, 1097 Irish and 308 English) and 4253 were negroes; (1910, census), 46,921. Springfield is served by the Cleveland, Cincinnati, Chicago & St Louis; the Pittsburg, Cincinnati, Chicago & St Louis; the Erie, and the Detroit, Toledo & Ironton railways, and by an extensive inter-urban electric system. The older portion of the city is in the narrow valley of Lagonda Creek, but from here the city has spread over the higher and more undulating surface farther back until it occupies an area of about $8\frac{1}{2}$ sq. m. Among the public buildings are the United States government building, the Clark county court house, the City building (the first floor of which is occupied by the city market), the Warder public library (established 1872), which in 1908 contained 25,000 volumes, the city hospital, and the city prison and workhouse. On hills near the city border are the Ohio state homes for the Masons, the Independent Order of Oddfellows, and the Knights of Pythias. The city park contains more than 250 acres, and in 1908 the city adopted plans for an extensive park system. Ferncliff cemetery is a picturesque burial-ground. On a hill on the north side of the city is Wittenberg College (Lutheran; 1845), which in 1909 had 35 instructors and 710 students. Springfield is in a productive farming region, and water power is provided by Lagonda Creek, so that manufactures closely related to agriculture have always been prominent. The value of the factory product in 1905 was $13,654,423, of which $4,051,167 was the value of agricultural implements, $2,914,493 of foundry and machine-shop products, and $1,025,244 of flour and grist-mill products. The municipality owns and operates the waterworks. Natural gas is piped from Fairfield county.

In 1799 Simon Kenton and a small party from Kentucky built a fort and fourteen cabins near Mad river 3 or 4 m. beyond the present western limits of the city. Later in the same year James Demint built a cabin on a hill-side overlooking Lagonda Creek. In 1801 he engaged a surveyor to plat a town here and soon after this the site of the Kenton settlement was abandoned. The new town was near the borderline that had been fixed between the Whites and the Indians, and the latter threatened trouble until 1807, when in a council held on a large hill in the vicinity, at which Tecumseh was the principal speaker for the Indians, peace was more firmly established. In 1818, when Clark county was erected, Springfield was made the county-seat. It was incorporated as a town in 1827, and in 1850 it was chartered as a city.

See E. S. Todd, *A Sociological Study of Clark County, Ohio* (Springfield, 1904).

SPRING-GUN, a device formerly in use against poachers and trespassers. Wires were attached to the trigger of a gun in such a manner that any one stumbling over or treading on them would discharge it and wound himself. Since 1827 spring-guns and all man-traps are illegal in England, except within a house between sunset and sunrise as a protection against burglars. Spring-guns are sometimes used to trap wild animals.

SPRINGTAIL, the common name of a group of small insects, so named from the presence of a pair of tail-like appendages at the end of the abdomen, which acts as a spring. When the insect is undisturbed these appendages are turned forwards and held in position by a catch beneath the abdomen; but in case of alarm they are kicked forcibly downwards and backwards, jerking the body into the air. This action may be rapidly repeated until a place of safety is reached. These insects usually live under fallen leaves, stones or the bark of trees, and sometimes occur in such quantities as to resemble patches of powder or dust. One species (*Podura aquatica*) may be seen floating in this way in masses upon the surface of standing water. Another (*Achorutes socialis*) may sometimes be found in abundance in the snow. Zoologically the springtails belong to the sub-order Collembola of the order Aptera (*q.v.*).

SPRING VALLEY, a city of Bureau county, Illinois, U.S.A., on the north bank of the Illinois River, in the northern part of the state, about 104 m. S.W. of Chicago. Pop. (1890), 3837; (1900), 6214 (2845 foreign-born); (1910) 7035. It is served by the Chicago, Burlington & Quincy, the Chicago, Rock Island & Pacific, the Chicago & North Western, and the Chicago, Ottawa & Peoria (electric) railways. Spring Valley is a shipping and distributing point for a large number of bituminous coal-mines in its vicinity. It was chartered as a city in 1886.

SPRUCE, *i.e.* spruce-fir, a coniferous tree belonging to the genus *Picea*, of which there are several species, such as the Norway spruce, *Picea excelsa*; the black spruce, *Picea nigra*, &c. (see Fir). The name has a curious origin, which explains also the particular meaning of the adjective "spruce," neatly dressed, smart in appearance, fine. From a number of early quotations given by Skeat (*Etym. Dict.*) it is clear that "spruce" a variant of "pruce," simply stood for Prussian; the form "spruce," rather than "pruce," being established partly by the German *Sprossen*, sprouts or young shoots (seen in *Sprossen-bier*, spruce beer, made of the sprouts of this fir).

SPRUE, a tropical disease, prevalent in India, China, Java, and the West Indies. It is described by Sir Patrick Manson as characterized by a peculiar, inflamed, superficially ulcerated, exceedingly sensitive condition of the mucous membrane of the tongue and mouth; great wasting and anaemia; and more or less diarrhoea, with pale and frothy fermenting stools. It is an obscure disorder, and the treatment recommended is rest and milk diet.

SPULLER, EUGÈNE (1835–1896), French politician and writer, was born at Seurre (Côte d'Or) on the 8th of December 1835, his father being a German who had married and settled in France. After studying law at Dijon he went to Paris, where he was called to the bar, and entered into close relations with Gambetta, collaborating with him in 1868 in the foundation of the *Revue politique.* He had helped Emile Ollivier in his electoral campaign in Paris in 1863, but when in 1869 Ollivier was preparing to "rally" to the empire he supported the republican candidate. During the siege of Paris he escaped from the city with Gambetta, to act as his energetic lieutenant in the provinces. After the peace he edited his chief's Parisian organ, the *République française*, until in 1876 he entered the Chamber of Deputies for the department of the Seine. He was minister of foreign affairs during part of the brief Gambetta administration, and subsequently one of the vice-presidents of the chamber, serving also on the budget commission and on a special industrial and agricultural inquiry. His Parisian constituents thought his policy too moderate on the clerical question, and he had to seek election in 1885 in the Côte d'Or, which in later years he represented in the Senate. He was minister of education, religion and the fine arts in the Rouvier cabinet of 1887, minister of foreign affairs under Tirard (1889–1890), and minister of education in 1894 in the Casimir-Périer cabinet. He died on the 28th of July 1896. His published works include some volumes of speeches and well-known studies of Ignatius Loyola (1876) and of Michelet (1876).

SPUR (A.S. *spura, spora*, related to *spornan, spurnan*, to kick, spurn; cf. M.H.G. *sporn*, mod. Ger. *Sporn*), an instrument attached to the heel of a rider's boot for the purpose of goading the horse. The earliest form of the horseman's spur armed the heel with a single prick. In England the rowel spur is shown upon the first seal of Henry III., but it does not come into general use until the 14th century. In the 15th century spurs appear with very long shanks, to reach the horse's flank below the outstanding bards. After this time, and until the beginning of the modern period of costume at the Restoration, they take many decorative forms, some of which remain in the great spurs worn by Mexican cavaliers. Gilded spurs were reckoned the badge of knighthood, and in the rare cases of ceremonious degradation they were hacked from the knight's heels by the cook's chopper. After the battle of Courtrai, in 1302, the victors hung up bushels of gilt spurs in the churches of Courtrai and Maestricht as trophies of what is still remembered by the Flemings as the *Goudensporendag*. For another reason the English named the French rout beside Thérouanne as the Battle of Spurs.

In architecture, a spur (Fr. *griffe*, Ger. *Knoll*), is the ornament carved on the angles of the base of early columns; it consists of a projecting claw, which, emerging from the lower torus of the base, rests on the projecting angle of the square plinth. It is possibly to these that Pliny refers (*Hist. Nat.* xxvi. 42) when speaking of the lizard and frog carved on the bases (*spirae*) of the columns of the temples of Jupiter and Juno in the Portico of Octavius; the earliest known example is that of Diocletian's palace at Spalato. In Romanesque work the oldest examples are those found on the bases in crypts, where they assumed various conventional forms; being, however, close to the eye, the spur soon developed into an elaborate leaf ornament, which in French 13th-century work and in the early English period is of great beauty; sometimes the spur takes the form of a fabulous animal, such as a griffin.

SPURGEON, CHARLES HADDON (1834–1892), English Nonconformist divine, was born at Kelvedon, Essex, on the 19th of June 1834. He was the grandson of an Essex pastor, and son of John Spurgeon, Independent minister at Upper Street, Islington. He went to school at Colchester and Maidstone, and in 1849 he became usher at a school in Newmarket. He joined the Baptist communion in 1851, and his work at once attested his "conversion." He began distributing tracts and visiting the poor, joined the lay preachers' association, and gave his first sermon at Teversham, near Cambridge. In 1852 he became pastor of Waterbeach. He was strongly urged to enter Stepney (now Regent's Park) College to prepare more fully for the ministry, but an appointment with Dr Joseph Angus, the tutor, having accidently fallen through, Spurgeon interpreted the *contretemps* as a divine warning against a college career. The lack of early systematic theological training certainly had a momentous effect upon his development. Broad in every other respect, he retained to the last the narrow Calvinism of the early 19th century. His powers as a boy preacher became widely known, and at the close of 1853 he was "called" to New Park Street Chapel, Southwark. In a very few months' time the chapel was full to overflowing. Exeter Hall was used while a new chapel was being erected, but Exeter Hall could not contain Spurgeon's hearers. The enlarged chapel at once proved too small for the crowds, and a huge tabernacle was projected in Newington Causeway. The preacher had recourse to the Surrey Gardens music hall, where his congregation numbered from seven to ten thousand. At twenty-two he was the most popular preacher of his day. In 1857, on the day of national humiliation for the Indian Mutiny, he preached at the Crystal Palace to 24,000 people. The Metropolitan Tabernacle, with a platform for the preacher and accommodation for 6000 persons, was opened for service on the 25th of March 1861. The cost was over £30,000, and the debt was entirely paid off at the close of the opening services, which lasted over a month. Spurgeon preached habitually at the Tabernacle on Sundays and Thursdays. He frequently spoke for nearly an hour, and invariably from heads and subheads jotted down upon half a sheet of letter paper. His Sunday sermons were taken down in shorthand, corrected by him on Monday, and sold by his publishers, Messrs Passmore & Alabaster, literally by tons. They have been extensively translated. Clear and forcible in style and arrangement, they are models of Puritan exposition and of appeal through the emotions to the individual conscience, illuminated by frequent flashes of spontaneous and often highly unconventional humour. In his method of employing illustration he is suggestive of Thomas Adams, Thomas Fuller, Richard Baxter, Thomas Manton and John Bunyan. Like them, too, he excelled in his vigorous command of the vernacular. Among more recent preachers he had most affinity with George Whitefield, Richard Cecil and Joseph Irons. Collected as *The Tabernacle Pulpit*, the sermons form some fifty volumes. Spurgeon's lectures, aphorisms, talks, and "Saplings for Sermons" were similarly stenographed, corrected and circulated. He also edited a monthly magazine, *The Sword and Trowel*; an elaborate exposition of the Psalms, in seven volumes, called *The Treasury of David* (1870–1885); and a book of sayings called *John Ploughman's Talks; or, Plain Advice for Plain People* (1869), a kind of religious *Poor Richard*. In the summer of 1864 a sermon which he preached and printed on *Baptismal Regeneration* (a doctrine which he strenuously repudiated, maintaining that immersion was only an outward and visible sign of the inward conversion) led to a difference with the bulk of the Evangelical party, both Nonconformist and Anglican. Spurgeon maintained his ground, but in 1865 he withdrew from the Evangelical Alliance. Subsequently in 1887 his distrust of modern biblical criticism led to his withdrawing from the Baptist Union. His powers of organization were strongly exhibited in the Pastors' College, the Orphanage (at Stockwell), the Tabernacle Almshouses, the Colportage Association for selling religious books, and the gratuitous book fund which grew up under his care. He received large money testimonials

(£6000 on his silver-wedding day and £5000 on his fiftieth birthday), which he handed over to these institutions. He died at Mentone on the 31st of January 1892, leaving a widow with twin sons (b. 1856). One of them, Rev. Thomas Spurgeon, after some years of pastorate in New Zealand, succeeded his father as minister of the Tabernacle, but resigned in 1908 and became president of the Pastors' College.

An *Autobiography* was compiled by his widow and his private secretary from his diary, sermons, records and letters (1897–1900).

SPURN HEAD, or SPURN POINT, a foreland of the North Sea coast of England, in Yorkshire, projecting across the mouth of the Humber. Its length is nearly 4 m. from the village of Kilnsea, but its breadth seldom exceeds 300 yds., and it rises only a few feet above sea-level. It is formed of sand and shingle, the débris of the soft coast of Holderness to the north, from which it is estimated that six million tons of material are annually removed by southerly currents along the shore. Deep water is found close off the seaward side of Spurn Head, the formation of which appears to have taken place within historic times, even since about the close of the 16th century. There are two lighthouses and a lifeboat station on the head.

SPURZHEIM, JOHANN CHRISTOPH [KASPAR] (1776–1832), German phrenologist, was born near Treves on the 31st of December 1776. He made the acquaintance of F. J. Gall while studying medicine in Vienna, and for some years assisted him in spreading his phrenological doctrines, but in 1813 the two separated. Spurzheim lectured with considerable success in England and France, and was extending his propaganda to the United States when he died at Boston, Massachusetts, on the 10th of November 1832. His works include: *Anatomie et physiologie du système nerveux* (1810–1820); *Observations sur la phrénologie* (1810); *The Physiognomical Systems of Drs Gall and Spurzheim* (1815), and *Essai philosophique sur la nature de l'homme* (1820). (See PHRENOLOGY.)

SPY, a commune near Namur, Belgium. Here in 1886, in Betche aux Roches cavern, Maximin Lohest and Marcel de Puydt found two nearly perfect skeletons (man and woman) at the depth of 16 ft., with numerous implements of the Mousterian type. All the human remains are now in the Lohest Collection, Liége. The skulls were characterized by enormous brows, retreating forehead, massive jaw-bones, rudimentary chin and large posterior molars. The skeletons were further marked by a divergent curvature of the bones of the fore-arm; the tibia were shorter than in any other known race, and stouter than in most; the tibia and femur, being so articulated that to maintain equilibrium the head and body must have been thrown forward, as in the gait of the larger apes. These characteristics justify placing "the man of Spy in the lowest category . . . the dentition is inferior to that of the neolithic man in France . . . approximates near to the apes, although there is still, to use the language of Fraipont and Lohest, an abyss between the man of Spy and the highest ape" (E. D. Cope, "The Genealogy of Man" in *The American Naturalist*, April 1893, p. 334). With the skeletons were found bones of extinct mammals, the woolly rhinoceros (*Rhinoceros tichorhinus*), mammoth (*Elephas primi-genius*), and the cave-bear (*Ursus spelaeus*).

See also *L'Homme contemporain du mammouth à Spy* (Namur, 1887); G. de Mortillet, *Le Préhistorique* (1900).

SPY (from "to spy" or "espy"; O. Fr. *espie*, *espier*, to spy, watch; cf. Ger. *spähen*, Lat. *specere*, to look; the Fr. term "espionage" is of course from the same source), in war—a person who, disguised or without bearing the distinguishing marks of belligerent forces, mixes with the enemy for the purpose of obtaining information useful to the army he is serving. As by the law of war a spy is liable, if caught, to the penalty of death, the Hague "Regulations respecting the Laws and Customs of War on Land" are very precise on the subject. A soldier not wearing a disguise is not a spy, though he may be found within the zone of the hostile army and though his object may be to obtain information; nor are soldiers or civilians spies who cross enemy lines openly carrying messages. This applies even to persons sent in balloons for the purpose of carrying despatches. In short, it is essential to the character of a spy that he should act clandestinely or on false pretences, that he should be caught within the zone of operations of the hostile belligerent forces, and that his object should be to obtain information for use against them (art. 29). The regulations also provide that he cannot be "punished" without previous trial (art. 30). Nor can he be treated as a spy if he is captured after he has rejoined his army. He must then be treated as an ordinary prisoner of war (art. 31). (T. BA.)

The term "spy" is applied also to those who in time of peace secretly endeavour to obtain information concerning the forces, armaments, fortifications or defences of a country for the purpose of supplying it to another country. Every country has always endeavoured to guard jealously its military and naval secrets, and with this object denies admittance to fortified places or arsenals to those who cannot produce the proper credentials. Notwithstanding the utmost precautions, it is impossible to prevent some amount of leakage to countries which are prepared to pay for information otherwise unobtainable. Consequently, most countries have legislation dealing with "spying" in time of peace. In the United Kingdom, the Official Secrets Act 1889 makes it a misdemeanour wrongfully to obtain information as to any fortress, dockyard, office, &c., of his majesty, or, having such information or any information relating to the naval or military affairs of his majesty, to communicate the same to any person to whom it ought not in the interest of the state to be communicated at the time. If the information is communicated, or intended or attempted to be communicated, to any foreign state, the offence becomes a felony. In Germany an imperial law of 1893 deals similarly with such an offence.

SQUADRON, a military and naval term for a body of mounted troops or a detachment of war vessels. The word is derived from *squadra*, a square, as a military term, according to Florio, applied to a "certain part of a company of souldiers of 20 or 25 whose chiefe was a corporal," and so called no doubt as being formed on parade or in battle array in squares. *Squadra*, square, is derived from the Low Latin *exquadrare*, an intensive form of *quadrare* (*quadrus*, four-cornered, *quattuor*, four). In military usage the term "squadron" is applied to the principal units into which a cavalry regiment is divided, corresponding to the company in an infantry battalion. The normal modern division of a cavalry regiment is into four squadrons of two to four troops each, this squadron numbering 120 to 200 men (see CAVALRY). In naval usage a squadron is a group of vessels either as forming one of the divisions of a fleet or as a separate detachment under a flag officer despatched on special service. In military use, "squad" (a shortened form of "squadron") is used of any small detachment of men detailed for drill, fatigue or other duty.

SQUAILS (from *skail* or *kail*, a ninepin), an old English game in which disks are snapped or struck with the palm from the edge of a table or board at a mark at its centre. Its early prototype was *shove-groat*, called also *slyp-groat* or *slide-thrift*, which in the 18th century went under the name of *jervis* or *jarvis*. This last variation was played on a table marked with chalk into alleys divided into squares numbered from 1 to 9 or 10, the object being to send a halfpenny into a high-numbered space. If it went beyond nothing was scored. The highest aggregate of a certain number of plays won. The most scientific development of this class of games is the modern *Shuffle-board* (*q.v.*).

SQUALL, the name given to any sudden increase of wind to gale force. Generally speaking a squall is understood to be of short duration, but the word "gust" would be used to indicate an increase of wind force of more transient character than a squall. Gusts may succeed one another several times within the compass of a minute. A squall may comprise a succession of gusts, with intervening partial lulls, and would last with varying intensity for some minutes at least. The distinction between gusts and squalls is best illustrated by the traces of a Dines pressure-tube anemograph. The trace reproduced in fig. 1 for an ordinary steady wind shows that the force of the wind is constantly oscillating. The general appearance of the trace is a ribbon which has a breadth proportional to the mean wind velocity. The breadth of the ribbon is also dependent upon the nature of the reference; the better the exposure the narrower the ribbon; for an anemograph at a coast station the ribbon is wider for a shore wind than for a sea wind.

From the records obtained at Scilly and Holyhead, Dr G. C. Simpson concluded that a wind of mean hourly velocity v was composed of alternations of gusts and lulls ranging on the average between limits $\cdot 5+1\cdot 2v$ and $-\cdot 5+\cdot 76v$ with occasional recurrences to extreme velocities of $1\cdot 5+1\cdot 3v$ and $-1\cdot 0+\cdot 65v$. In other words, the average range of the ribbon is $\cdot 5+\cdot 45v$ for the two stations during the hour when the mean velocity is v, and the extreme range within the same period is $2\cdot 0+\cdot 68v$.

The differences of gust velocity at stations with different exposures may be illustrated by quoting the breadth of the ribbon for a 30 m. wind at the following stations:—

Southport (Marshside)	10 m.	
Scilly	15 „	
Shoeburyness	20 „	(from W.)
„	10 „	(from E.N.E.)
Holyhead	15 „	
Pendennis Castle (Falmouth)	8 „	(from S.)
„ „ „	16 „	(from W.)
Aberdeen	30 „	(from N.W.)
Alnwick Castle	25 „	
Kew	30 „	

Fig. 2 represents a succession of squalls occurring in an ordinary gusty wind; the squalls succeed one another with fair regularity about every twenty minutes and last in full force for a few minutes. A

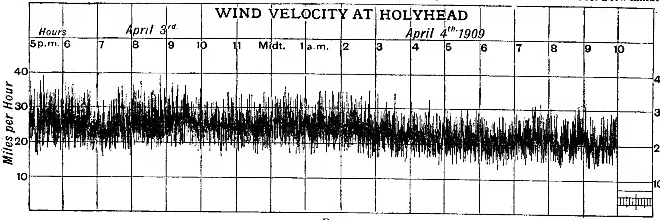

FIG. 1.

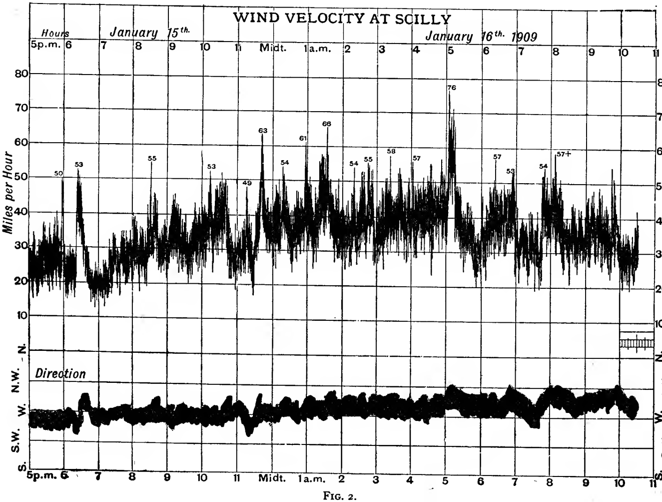

FIG. 2.

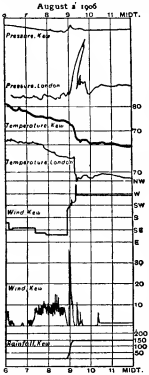
succession of squalls of this kind is a common experience with westerly wind at Scilly, and the onset of squalls is generally associated with the veering of the wind to the north-west. Changes in wind velocity, either in the form of gusts or squalls, are generally associated with some change in direction of the wind, but the relation between the changes in gusts have not yet been studied.



(Redrawn by permission from the *British Association Report*, 1908.)

FIG. 3.—Variation of Meteorological Elements in a Line Squall.

A characteristic of squalls is the suddenness with which the increase of wind velocity occurs. At sea the ruffling of the surface can be seen travelling over the water, and the wind producing it and travelling with it strikes a sudden blow when it reaches a ship. If squalls are of sufficient violence to do damage to trees or buildings their progress can be traced in a like manner over the land.

These phenomena are exhibited in their most striking form in "line squalls." The characteristic feature of a line squall is that a number of places arranged, roughly speaking, in a straight or slightly curved line across the country experience a similar sequence of events at the same time, and the line of action sweeps across the country as a front advancing nearly uniformly throughout its length. This march of a linear front gives the impression of a wave or bore with an advancing front hundreds of miles long, sweeping over the country with a velocity that can be identified from the time of occurrence of the various changes at different places. The associated events are very well marked by those recorded for the line of squall of the 2nd of August 1906 (fig. 3). They comprise a sudden increase of wind with a veer of direction of 45° to 90°, a sudden rise of pressure known in France as the *crochet d'orage*, and in Germany as the *Gewitter Nase*, a pronounced and permanent fall of temperature, and a shower of rain, hail or snow. While these various phenomena are indicated all along the advancing line their intensity may be very different at different points along it. The squall often exhibits greater violence in the middle portion, and it becomes more intense as the whole line advances. In the most fully developed portions the weather phenomena take the form of thunderstorms with violent wind and rain. The course of events in a typical line squall has been most carefully worked out by R. G. K. Lempfert in a paper on the "Line Squall" of the 8th of February 1906 (*Quart. Journ. Roy. Met. Soc.* vol. xxxii.). Fig. 4 (reproduced from the papers) shows the successive positions of the line of the front from which its rate of travel can be estimated. The line of advance of a line squall is generally from some point between south and north on the western side, the change of wind being from a warm southerly or westerly wind to a colder westerly or northerly one. So far as is known to the writer there is no case of a line squall exhibiting a backing wind. The date and direction of advance appear to be, generally speaking, those of the final wind, but in cases where the thunderstorms are developed there is a local violence of the wind bearing no relation to the isobaric distribution of the final wind.

Endeavours have been made to explain the phenomena of line squalls as due to vortex motion of particular character. The violent wind blowing out in front of the storm is part of the circulation of a vortex with horizontal axis. It supplies the air for the rainfall of the stations in front. Its place is taken by descending air at the back, which becomes in its turn the surface supply for stations farther in. But such an explanation seems in many ways incomplete. Although perhaps if the wind velocities in a vertical plane were plotted there might be some evidence of circulation in the mathematical sense by integrating round a closed curve, yet the idea of circulation in a vertical plane as suggesting the primary constitution of the phenomena is very inadequate. The change of air which takes place during the passage of the line squall is altogether different from that which we would get by passing the surface air through a complete vertical cycle and condensing a large quantity of water vapour on the way. If vertical circulation were complete the air would

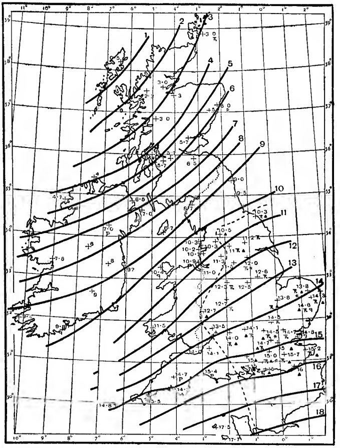


FIG. 4.—Times of occurrence of sudden meteorological changes, and isochronous lines showing the advance of the squall. The hours are numbered consecutively from 1 to 18, starting at 1 a.m. (Feb. 8), and the minutes are expressed as decimal fractions of an hour. Hail and thunder storms occurred in the region to the east of the dotted line.

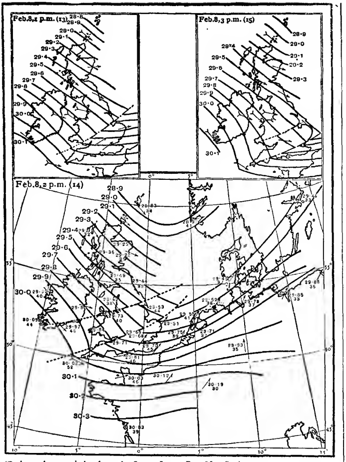
return to the surface warmed and dried. A few revolutions would produce a very considerable elevation of temperature. The air which remains after the passage of a line squall is, however, distinctly colder, of an entirely different kind from that which it replaces and, in those cases which have been investigated, can be traced back to a different point of the compass. Moreover, the smallness of vertical dimensions in the atmosphere as compared with the horizontal dimensions makes it difficult to allow that there is really room for an effective vortex with a horizontal axis. To carry air up 5 m. and bring it back again would practically deprive it of all its moisture and raise its temperature 72° F. Yet 5 m. would be a very small allowance for the horizontal spread of the phenomena of the squall.

The sudden replacement of warm air by cold with a change of wind seems much more likely to be associated with the flooding of the country by an advancing sweep of cold air. The pressure changes are continuous in the old layer and in the new layer, but discontinuous with varying degrees of discontinuity along the line of junction, where instability of the upper air may be set up. Fig. 5 shows the discontinuity of pressure in the example discussed by Mr Lempfert. It is clear that as the discontinuity of pressure becomes accentuated there arise



(Redrawn by permission from the *Quart. Journ. Roy. Met. Soc.*)

Fig. 5.—Distribution of Pressure (Feb. 8, 1906). Isobars are shown for each 0·1 in.

Fig. 6.—Records of wind velocity on June 1, 1908.

in the localities on the line of advance very steep pressure gradients for which there are corresponding winds. The violent winds may therefore be attributed to the breakdown of the dynamical system under the stress of these local differences of pressure.

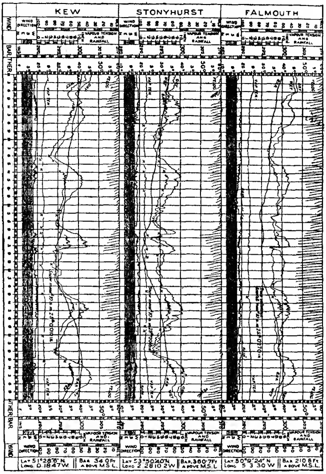
From this point of view the phenomena of the line squall are to be regarded as a development of the ordinary phenomena of the V-shaped depression. A sudden change of wind and a line of rain that pass over the country with the velocity of the same order as that of the following wind are quite common features of the S.W. quadrant of a cyclonic depression, and they, too, seem to point to the juxtaposition of currents of different temperature coming from different regions but forming adjacent components of supply for the depression.

Examples of all degrees between the comparatively unimportant rain line and the most violent tornado-like squall could be put side by side with cases in which the typical pressure, temperature and weather changes are accompanied by a sudden lull in the wind, as in the example quoted in the *Life History of Surface Air Currents* (M. O. publication, No. 174, 1906). An example of a line squall in its most violent and destructive form is shown in the records for the 1st of June 1908. In the record for Kew the squall of wind which destroyed a number of the trees of Bushey Avenue is shown as lasting for a very long period (fig. 6).

A line squall of historic interest is that which capsized H.M.S. "Eurydice" off the Isle of Wight on the 24th of March 1878. The occurrence is discussed by the Hon. Ralph Abercromby in 1884 (*Quart. Journ. Roy. Met. Soc.* x. 172) and previously by the Rev. Mr Clementhey (*Symon's Met. Mag.*, April 1878). The shift of wind in this case appears to have been from west to north, and the change in the wind was accompanied by the transitions from fine blue sky to snow. The records at the seven observatories belonging to the Meteorological Council are reproduced in the *Quarterly Weather Report*, from which fig. 7 is taken.

Whatever explanation may be given of the cause and origin of the phenomena of line squalls, it must take account of the fact that a first squall is often succeeded by others of a similar character but often of less intensity than the first. After the sudden shift of wind, with accompanying weather changes, the conditions seem to revert more or less to the original state. The warm southerly wind reasserts itself, but is driven out again by another attack, and ultimately the cold wind holds the field. It is easy to suggest, but at present not easy to verify, the course of replacement of the warm wind. Upper air observations in such circumstances with kites or manned balloons are dangerous, both for the apparatus and the observer; but it may be possible to trace the actual course of events by the records of rounding balloons supplemented by observations of the motive balloon by means of theodolites.

Little has been said about the actual force of the wind in gusts or squalls, and in the present state of anemometry it is difficult to



(By permission of the Controller of His Majesty's Stationery Office.)

Fig. 7.—"Eurydice" Squall, from the *Quarterly Weather Report.*

regard the figures hitherto obtained as final; moreover, the large wind force in squalls is probably subject to large local variations, the difference between the record of the squall of the 1st of June 1908 at Kew and Shepherd's Bush suggests that it may have been much stronger at Bushey, where the damage was done. The highest velocity in a gust hitherto recorded upon instruments belonging to the office is 106 5 m. per hour at Pendennis Castle on the 14th of March 1905. Gale force is defined for the purposes of the meteorological office as that of a wind which has an average velocity during an hour of 38 m. per hour. According to Simpson's results at Scilly or Holyhead, where the exposure is good, a wind that just got within the reckoning of gales would reach 44 m. per hour in the ordinary gusts, with occasional records of 51 m. per hour. Squalls with velocities reaching 55 m. per hour are not uncommon, and the range of wind velocity which constitutes a squall may be anything between 40 m. an hour and upwards of 100 m. an hour. (W. N. S.)

SQUAW, the anglicized word for woman among the North American Indians; the Massachusetts Indian form is *squa* or *schqua*, the Narraganset *squăwo*, the Cree *eskwuo*, Delaware *ochqueu*, *khqueu*, &c. It is also used in composition with names of animals to denote the female.

SQUIB, supposed to be derived from the German word *schieben*, to push or shove forward with a sliding movement, the name for a projected kind of firework that is flung out of a groove and breaks with a flash and a clatter. Hence, in the literary sense, a squib is a slight satirical composition put forth on an occasion; and it is intended that it should make a noise by its explosion, not by the possession of any permanent importance. Steele says, in the *Tatler*, that "squibs are those who in the common phrase of the world are call'd libellers, lampooners and pamphleteers," showing that, at the beginning of the 18th century, the man who composed the satire, as well as the satire itself, was called a squib Swift speaks of the rapidity with which these little literary fireworks flew about from place to place, and he himself was a proficient in the making of noisy squibs. Perhaps the best type of a squib in English literature is Gray's *Candidate*, which was written and circulated among the electors in 1764, when Lord Sandwich was canvassing for the office of high-steward of the university of Cambridge. The object of this poem was, by ridicule and defamation, to injure Lord Sandwich's prospects of success. When once the election was over the verses served no further purpose, and they have survived simply in consequence of their fluent wit and of the reputation of the great poet who composed them. (See also LAMPOON.)

SQUILL, the name under which the bulbous root of *Urginea Scilla* is used in medicine. It belongs to the natural order Liliaceae. The name of "squill" is also applied by gardeners to the various species of *Scilla*. The medicinal squill is a native of the countries bordering the Mediterranean, and grows from the sea-level up to an elevation of 3000 ft. The bulbs are globular and of large size, often weighing more than 4 ℔. Two varieties are met with, the one having white and the other pink scales. They are collected in August, when they are leafless, the membranous outer scales being removed and the fleshy portion cut transversely into slices and dried in the sun. These are then packed in casks for exportation. They are chiefly imported into the United Kingdom from Malta. When reduced to powder and exposed to the air the drug rapidly absorbs moisture and cakes together into a hard mass.

Squill has been used in medicine from a very early period. The ancient Greek physicians prescribed it with vinegar and honey almost in the same manner as it is used at present. The composition of the drug, first efficiently studied by Merck in 1878, is very complex. The chief constituent is *scillitoxin*, a bitter and intensely irritant principle. A somewhat similar substance, *scillipiain*, is also physiologically active. The bitter glucoside *scillin*, or *scillain*, is unimportant. The bulb also contains mucilage, and a considerable quantity of an irritant resin. It has been shown that a definite action on the heart is not obtainable unless so large a dose of squill is given that some gastro-intestinal irritation or even inflammation is set up by this resin. The dose of squill is from 1 to 3 grains. Of the numerous pharmacopoeial preparations only three are of any importance: the syrup of squill, composed of one part of squill, eight of dilute acetic acid and four of sugar; the *Pilula Ipecacuanhae cum Scilla*, in which ipecacuanha and opium are the chief constituents; and the tincture of squill, which is still widely used, made by macerating one part of squill with five of alcohol. The action of the drug is that of a cardiac stimulant, with three important further properties all dependent on its irritant constituents. Even in small doses, such as will not affect the heart, it is a gastro-intestinal, a bronchial and a renal irritant. The two latter properties constitute it a powerful expectorant and a fairly active diuretic. The drug must not be given alone, owing to its irritant action. It is very frequently given as a diuretic in cardiac cases in the form of a pill containing one grain each of mercury, digitalis and squill. Combined with a sedative, such as opium, it may be given in chronic bronchitis. It must not be given in acute bronchitis, which it only aggravates; nor in phthisis, which is invariably accompanied by a hypersensitive state of the alimentary tract. For similar reasons squill should not be given in any form of Bright's disease. The textbook prohibition against its use in acute Bright's disease should certainly be extended to chronic nephritis in all its forms. The use of this irritating drug, while still extensive, is yearly diminishing. It does not accomplish anything that may not otherwise be achieved at less cost to the secreting surfaces of the patient.

An allied species, *Urginea indica*, is used in India in the same manner as the European species. The true squills are represented in Great Britain by two species, *Scilla autumnalis* and *S. verna*. The former has a racemose inflorescence and leaves appearing in autumn after the flowers; the latter has the flowers arranged in a corymbose manner, leaves appearing in spring, and is confined to the sea-coast. Several species are cultivated in gardens, *S. bifolia* and *S. sibirica* being remarkable for their beautiful blue flowers, which are produced in early spring; Chinese squill is *S. chinensis*, a half-hardy species; Roman squill is a popular name for species of *Bellevalia*, a genus now generally included in *Hyacinthus*; striped squill is *Puschkinia scilloides*, a liliaceous plant resembling the squill in habit.

SQUINCH, possibly a corruption of sconce (French equivalents are *pendentive*, *trompe*), the term in architecture applied to a corbelling out by means of arched rings in stone thrown across the angles of a square tower, to carry an octagonal spire or a dome. The earliest examples are found in the palaces of Serbittan and Firuzabad constructed by the Sassanian dynasty (A.D. 350–450), and in the mosque at Damascus, where it takes the form of a niche. In early French Romanesque work a small niche with additional rings above is employed; a greater importance is sometimes given by small shafts at the sides, of which there are examples in the Coptic churches of Egypt, and in France in the cathedral at Le Puy and the church of St Martin at Dijon. (See PENDENTIVE.)

SQUINT (possibly connected with Swed. *svinka*, to flinch; O. Eng. *swiccan*, avoid), properly an adjective meaning looking different ways, hence oblique, indirect vision, particularly a strabismus, an affection of the eyes consisting in non-coincidence of the optic axes (see EYE, § *Diseases*; and VISION). In architecture "squint" is used of a slit or opening usually on one or both sides of the chancel arch, giving a view of the altar from the transepts or aisles; it is also styled "hagioscope" (*q.v.*).

SQUIRE, an abbreviated form of "esquire" (*q.v.*), originally with the same meaning of an attendant on a knight. In this form, however, the word has developed certain special connotations. Thus in England it is used partly as a courtesy title, partly as a description of the chief landed proprietor, usually the lord of the manor, in a parish the lesser proprietors being "gentlemen" or yeomen. In some parts also it is not uncommon for the title of "squire" to be given to small freeholders of the yeoman class, known in Ireland half contemptuously as "squireens." In the United States the title has also survived as applied to justices of the peace, local judges and other dignitaries in country districts and towns. In another sense "squire" has survived in its sense of "attendant," "to squire" being used so early as Chaucer's day as synonymous with "to wait upon." A "squire of dames" is thus a man very attentive to women and much in their company. Footpads and highwaymen were termed sometimes "squires of the pad" as well as "gentlemen of the road."

SQUIRREL (Fr. *écureuil*), properly the name of the well-known red, bushy-tailed British arboreal mammal, *Sciurus vulgaris*, typifying the genus *Sciurus* and the family Sciuridae, but in a wider sense embracing all the rodents included in this and a few nearly allied genera. For the characteristics of the family Sciuridae and the different squirrel-like genera by which it is represented, see RODENTIA.

What may be called typical, that is to say arboreal, squirrels are found throughout the greater part of the tropical and temperate regions of both hemispheres, although they are absent both from Madagascar and Australasia. The species are both largest and most numerous in the tropics, and reach their greatest development in the Malay countries. Squirrels vary in size from animals no larger than a mouse, such as *Nannosciurus soricinus* of Borneo, or *N. minutus* of West Africa, to others as large as a cat, such as the black and yellow *Ratufa bicolor* of Burma and the Malay area. The larger species, as might be expected from their heavier build, are somewhat less strictly arboreal in their habits than the smaller ones. The common squirrel, whose habits are too well known to need special description, ranges over the whole of Europe and Northern Asia, from Ireland to Japan, and from Lapland to North Italy; but specimens from different parts of this wide range differ so much in colour as to constitute distinct races. Thus, while the squirrels of north and west Europe are of the bright red colour of the British animal, those of the mountainous regions of southern Europe are of a deep blackish grey; while those from Siberia are a clear pale grey colour, with scarcely a tinge of rufous. There is also a great seasonal change in appearance and colour in this squirrel, owing to the ears losing their tufts of hair and to the bleaching of the tail. The pairing time of the squirrel is from February to April; and after a period of gestation of about thirty days the female brings forth from three to nine young. In addition to all sorts of vegetables and fruits, the squirrel is exceedingly fond of animal food, greedily devouring mice, small birds and eggs. The squirrels of the typical genus *Sciurus* are unknown in Africa south of the Sahara, but otherwise have a distribution co-extensive with the rest of the family.

Although the English squirrel is a beautiful little animal, it is surpassed by many of the tropical members of the group, and especially by those of the Malay countries, where nearly all the species are brilliantly marked, and many are ornamented

The Burmese Red-bellied Squirrel (*Sciurus pygerythrus*).

with variously coloured longitudinal stripes along their bodies. Every one who has visited India is familiar with the pretty little striped palm-squirrel, which is to a considerable extent a partially domesticated animal, or, rather, an animal which has taken to quarter itself in the immediate neighbourhood of human habitations. It has been generally supposed that there is only one palm-squirrel throughout India, but there are really two distinct types, each with local modifications. The first or typical palm-squirrel, *Funambulus palmarum*, inhabits Madras, has but three light stripes on the back, and shows a rufous band on the under-side of the base of the tail. In Pennant's palm-squirrel, *F. pennanti*, on the other hand, there is a pair of faint additional lateral white stripes, making five in all, and the under-surface of the tail is uniformly whitish olive. As this species has been obtained in Surat and the Punjab, it is believed to be the northern type. One Oriental species (*Sciurus caniceps*) presents almost the only known instance among mammals of the assumption during the breeding season of a distinctly ornamental coat, corresponding to the breeding plumage of birds. For the greater part of the year the animal is of a uniform grey colour, but about December its back becomes a brilliant orange-yellow, which lasts until about March, when it is again replaced by grey. The squirrel shown in the illustration is a native of Burma and Tenasserim, and is closely allied to *S. caniceps*, but goes through no seasonal change of colour. Another Burmese squirrel, *S. haringtoni*, differs as regards colour in a remarkable manner from all other known members of the group. It is a medium-sized species of a pale creamy buff colour above, lighter beneath, and with a whitish tail, while it is further characterized by the absence of the first upper premolar, which shows that it is not an albino or pale variety. Two examples were obtained by Captain H. H. Harington, of one of the Punjabi regiments, on the Upper Chindwin river. It may be added that generic subdivisions of the squirrels are based mainly on the characters of the skull and teeth. That they are essential is evident from the circumstance that the African spiny squirrels *Xerus* (see SPINY SQUIRREL) come between *Sciurus* and some of the other African genera. (R. L.*)

SQUIRREL MONKEY, the English name of a small golden-haired South American monkey, commonly known as *Chrysothrix sciurea*, and also applied to the two other members of the same genus, whose collective range extends from Costa Rica to Bolivia and Brazil. It has, however, been proposed to transfer the name *Chrysothrix* to the marmosets of the genus *Hapale*, to which it is stated to have been originally applied, and to replace it by *Saimiris*. The squirrel-monkeys were formerly classed with the douroucoulis (see DOUROUCOULI), but, on account of their brain-structure, they have been transferred to the Cebinae (see CAPUCHIN-MONKEY), from the other members of which they differ by their practically non-prehensile tails and smaller size, while they are further distinguished by their comparatively large eyes and the backward prolongation of the hinder part of the head. They are exceedingly pretty little monkeys. (See PRIMATES.) (R. L.*)

SRINAGAR, capital of the state of Kashmir, in Northern India, 5250 ft. above sea-level, on both banks of the river Jhelum, which winds through the city with an average width of 80 yds. and is crossed by seven wooden bridges. The houses occupy a length of about 3 m. and a breadth of about 1½ m. on either side of the river; but the greater part of the city lies on the right bank. No two buildings are alike. The curious grouping of the houses, the frail tenements of the poor, the substantial mansions of the wealthier, the curious carving of some, the balconies of others, the irregular embankment and the mountains in the background, form a quaint and picturesque spectacle. Area, 3795 acres. Pop. (1901), 122,618. The city is exposed to both fire and flood. In 1893 six of the seven bridges were swept away, and great damage was again caused in 1903. A regular water-supply has been provided. The artisans of Srinagar enjoy a high reputation. Unfortunately, the historic industry of shawl-weaving is now practically extinct. The loss of the French market after the war of 1870 was followed by the famine of 1877–1879, which drove many of the weavers into the Punjab, and the survivors have taken to the manufacture of carpets. Other industries are paper, leather, papier mâché, silver and copper ware, wood-carving and boat-making. The three chief routes of communication with India are: (1) along the Jhelum valley to Murree and Rawalpindi, which has been opened throughout for wheeled traffic (195 m.); (2) over the Banihal pass (9200 ft. above the sea) to Jammu (163 m.); (3) over the Pir Panjal pass (11,400 ft.) to Gujrat (180 m.).

See Sir Walter R. Lawrence, *The Valley of Kashmir* (1895); M. A. Stein, *Chronicle of the Kings of Kashmir* (1900).

SRIRANGAM, or SERINGHAM, a town of British India, in Trichinopoly district, Madras presidency, 2 m. N. of Trichinopoly city. Pop. (1901), 23,039. It stands on an island of the same name, formed by the bifurcation of the river Cauvery and by the channel of the Coleroon. The town is celebrated for its great temple, dedicated to Vishnu, composed of seven square enclosures, one within another, and 350 ft. distant from each other. Each enclosure has four gates with high towers, placed one in the centre of each side opposite to the four cardinal points. The successively widening enclosures and the greater elaboration of the outer as compared with the inner buildings mark the progress of the shrine in fame and wealth. The outer wall of the temple is not less than 4 m. in circumference. Not far distant is the smaller but more beautiful Jambukeswaram, a temple dedicated to Siva. From 1751 to 1755 the island and its pagodas were the object of frequent contests between the French and the English.

STAAL, MARGUERITE JEANNE CORDIER DELAUNAY, BARONNE DE (1684–1750), French author, was born in Paris on the 30th of August 1684. Her father was a painter named Cordier. He seems to have deserted her mother, who then resumed her maiden name, Delaunay, which was also adopted by her daughter. She was educated at a convent at Evreux, of which Mme de la Rochefoucauld, sister of the author of the *Maximes*, was superior. Here she became attached to Mme de Grieu, who, being appointed abbess of the convent of St Louis at Rouen, took her friend with her. Mlle Delaunay lived there until 1710 in the enjoyment of the utmost consideration. There she held a little court of her own, which included Brunel, the friend of Fontenelle, the sieur de la Rey and the abbé Vertot. She describes her own first passion for the marquis de Silly, the brother of a friend with whom she was visiting. Her affection was not returned, but she entered on a correspondence with him in which she plays the part of director. After the death of her patron, Mme de Grieu, poverty compelled her to enter the household of the duchesse du Maine at Sceaux in the capacity of *femme de chambre*. Her literary talent soon manifested itself in the literary court of the duchess, and secured for her, among other friendships, the somewhat undesirable admiration of the abbé Chaulieu. The duchess is said, but chiefly on the waiting-lady's own authority, to have been not a little jealous of her attendant. Enough, however, is known of the duchess's imperious and capricious temper to make it improbable that her service was agreeable. Mlle Delaunay, however, enjoyed a large share of her confidence and had a considerable share in drawing up the *Mémoire des princes légitimes* which demanded the meeting of the states-general. She was implicated in the affair of the Cellamare conspiracy, and was sent in 1718 to the Bastille, where she remained for two years. Even here, however, she made conquests, though she was far from beautiful. Her own account of her love for her fellow prisoner, the chevalier de Ménil, and of the passion of the chevalier de Maisonrouge, her gaoler, for her, is justly famous. She returned on her liberation to the service of the duchess, who showed no gratitude for the devotion, approaching the heroic, that Mlle Delaunay had shown in her cause. She received no promotion and still had to fulfil the wearisome duties of a waiting-maid. She refused, it is said, André Dacier, the widower of a wife more famous than himself, and in 1735, being then more than fifty, married the Baron de Staal. Her dissatisfaction with her position had become so evident that the duchess, afraid of losing her services, arranged the marriage to give Mlle Delaunay rank sufficient to allow of her promotion to be on an equality with the ladies of the court. On this footing she remained a member of the household. It was at this time that she became the friend and correspondent of Mme du Deffand. She died at Gennevilliers on the 15th of June 1750. Her *Mémoires* appeared about five years later, and have often been reprinted, both separately and in collections of the memoirs of the 17th and 18th centuries, to both of which the author belonged both in style and character. She has much of the frankness and seductive verve of Mme de Sévigné and her contemporaries, but more than a little alloyed with the *sensibilité* of a later time. It may be doubted whether she does not somewhat exaggerate the discomforts of her position and her sense of them. In her lack of illusions she was a child of the 18th century. Sainte-Beuve says that the most fit time for the reading of the *Mémoires* is the late autumn, under the trees of November. But her book is an extremely amusing one to read, as well as not a little instructive. The humours of the "court of Sceaux" are depicted as hardly any other society of the kind has ever been. "Dans cet art enjoué de raconter," says Sainte-Beuve, "Madame de Staal est classique."

Besides her *Mémoires* Mme de Staal left two excellent short comedies, performed at the court of Sceaux, and some letters, the answers to which are in some cases extant, and show, as well as the references of contemporaries, that the writer did not exaggerate her own charm. Her *Mémoires* were translated by S. Bathurst (1877) and by C. H. Bell (1892). See the edition (1877) of her *Mémoires* by M. de Lescure.

STABIAE, an ancient town of Campania, Italy, on the coast at the east extremity of the Gulf of Naples (mod. Castellammare di Stabia). It was dependent upon Nuceria Alfaterna (*q.v.*) until it joined the revolt against Rome in the Social War (90 B.C.). In 89 it was taken and destroyed by Sulla, and its territory given to Nuceria as a reward for fidelity to Rome. The place, however, continued to be visited for its natural beauties, its mineral springs and its pure milk. Remains of fine villas have been found about half a mile to the east of the modern town, and also the remains of a temple to the genius of Stabiae, which no doubt occupied the same site as it had done in Oscan times. None of these remains is now visible. The town was destroyed by the eruption of A.D. 79 (in which the elder Pliny met his death), but was soon rebuilt on the site now occupied by the modern Castellammare. Above the town on the east is the Mons Lactarius (from *lac*, milk). Here took place the battle between Narses and Teias in A.D. 553, which put an end to the Gothic domination in Italy.

See M. Ruggiero, *Scavi di Stabia del 1749 al 1782* (Naples, 1881); J. Beloch, *Campanien*, 2nd ed. p. 248 sqq. (Breslau, 1890). (T.As.)

STABLE, a building in which horses are kept, including the stall in which they stand, furnished with manger and rack, the room in which the harness is kept and attended to, the loft in which the hay and corn are stored, and other accessory rooms, &c. (See HORSE.) This is the current usage, but the word was formerly applied, as was the Latin *stabulum*, *i.e.* standing-place (from *stare*, to stand), to a stall or enclosure for all kinds of domestic animals, cows, sheep, &c. The adjective "stable," meaning firmly established, comes directly from Latin *stabilis*, also from *stare*, to stand.

STADE, BERNHARD (1848–1906), German Protestant theologian, was born on the 11th of May 1848, at Arnstadt, in Thuringia. He studied at Leipzig and Berlin, and in course of time became (1875) professor ordinarius at Giessen. Once a member of Franz Delitzsch's class, he became a convinced adherent of the newest critical school. In 1881 he founded the *Zeitschrift für alttestamentliche Wissenschaft*, which he continued to edit; and his critical history of Israel (*Geschichte des Volks Israel*, 2 vols., 1887–1888; vol. ii. in conjunction with Oscar Holtzmann) has made him very widely known. With C. Siegfried he has revised and edited the Hebrew lexicon, *Hebr. Wörterbuch zum Alten Testament* (1892–1893). Stade's other works include *Über die alttestamentlichen Vorstellungen vom Zustand nach dem Tode* (1877), *Lehrbuch der hebr. Grammatik* (vol. i., 1879), *Ausgewählte akademische Reden und Abhandlungen* (1899), and *Biblische Theologie des Alten Testaments* (1905, &c.). He died on the 6th of December 1906.

See O. Pfleiderer, *Development of Theology* (1890).

STADE, a town of Germany in the Prussian province of Hanover, situated on the navigable Schwinge, $3\frac{1}{2}$ m. above its confluence with the Elbe, 20 m. N.W. of Hamburg on the railway to Cuxhaven. Pop. (1905), 10,837. It carries on a number of small manufactures and has some shipping trade, chiefly with Hamburg, but the rise of Harburg has deposed it from its former position as the chief port of Hanover. In the neighbourhood are deposits of gypsum and salt. The fortifications, erected in 1755 and strengthened in 1816, were demolished in 1882.

According to the legend, Stade was the oldest town of the Saxons and was built in 321 B.C. Historically it cannot be traced farther back than the 10th century, when it was the capital of a line of counts. In the 13th century it passed to the archbishopric of Bremen. Subsequently entering the Hanseatic League, it rose to some commercial importance.[1] In 1648 Stade became the capital of the principality of Bremen under the Swedes; and in 1719 it was ceded to Hanover, the fate of which it has since shared. The Prussians occupied it without resistance in 1866.

See Jobelmann and Wittpennig, *Geschichte der Stadt Stade* (Stade, 1898).

STADION, JOHANN PHILIPP KARL JOSEPH (1763–1824), Austrian statesman, entered the diplomatic service and rose early to a high position. In 1790–1793 he was ambassador in London. After some years of retirement he was entrusted (1800) with a mission to the Prussian court, where he endeavoured in vain to effect an alliance with Austria. He had greater success as envoy at St Petersburg, where he played a large part in the formation of the third coalition against Napoleon (1805). Notwithstanding the failure of this alliance he was made foreign minister, and in conjunction with the archduke Charles pursued a policy of quiet preparation for a fresh trial of strength with France. In 1808 he abandoned the policy of procrastination, and with the help of Metternich hastened the outbreak of a new war. The unfortunate results of the campaign of 1809 compelled his resignation, but in 1813 he was commissioned to negotiate the convention which finally overthrew Napoleon. The last ten years of his life were spent in a strenuous and partly successful attempt to reorganize the disordered finances of his country.

See A. Beer, *Zehn Jahre österreichischer Politik, 1801–1810* (Leipzig, 1877); *Die Finanzen Oesterreichs im 19 Jahrhundert* (Prague, 1877); Krones, *Zur Geschichte Oesterreichs, 1792–1816* (Gotha, 1886).

STADIUM, the Latin form of this Greek name for a standard of length, a stade = 100 ὀργυιαί (about 6 ft., or 1 fathom) = 6 πλέθρα (100 Gr. about 101 Eng. ft.), equivalent to about 606 Eng. ft.; as being about one-eighth of the Roman mile, it is often translated by "furlong." The course for the foot-race at Olympia (*q.v.*) was exactly a stade in length, and hence the name was given to the Greek foot-race and to the amphitheatre in which the races took place (see GAMES, CLASSICAL).

STADTHOLDER (Du. *stadhouder*, a delegate or representative), the title of the chief magistrate of the seven states which formed the United Netherlands by the union of Utrecht in 1579. Though the word *stad* means a town, it has also the force of the kindred English "stead." A *stadhouder* was not the governor of a "stad" or "stead" in the sense of a place or town. He was in the place, or stead, of the sovereign. The word is translated into Latin by *legatus*, *gubernator* and *praefectus*. The office of stadtholder is a *proconsulatus*, and the High German equivalent is *Statthalter*, a delegate. When the northern Netherlands revolted from Philip II. of Spain, who had inherited his sovereign rights from the house of Burgundy (see NETHERLANDS: *History*), the *stadhouder* passed from being the representative of an absent sovereign prince and became the chief magistrate of the states in whom the sovereignty resided. Six of the seven states forming the confederation of the United Netherlands took as their stadtholder William of Orange-Nassau, called "the Silent," and his descendants during three generations. The seventh, Friesland, had for stadtholder William's brother, John "the Old," and his descendants. The younger line became stadtholders of the other states after the extinction of the elder, and were the ancestors of the present royal family of the Netherlands. Though the stadtholders of the house of Orange-Nassau were of princely rank and intermarried with the royal families of Europe, they were not sovereign princes. They exercised large administrative powers, and commanded the land and sea forces, but it was with delegated authority given them by each state in domestic affairs, and by the states-general of the confederation in all common and foreign affairs. The states-general and some of the individual states not only claimed but exercised the right of suspending the stadtholdership, as for instance after the death of William II., 1650, and of William III., 1702.

[1] The Stade Elbe-dues (Stader Elbezoll) were an ancient impost upon all goods carried up the Elbe, and were levied at the village of Brunshausen, at the mouth of the Schwinge. The tax was abolished in 1267 by the Hanseatic League, but it was revived by the Swedes in 1688, and confirmed by Hanover. The dues were fostered by the growing trade of Hamburg, and in 1861, when they were redeemed (for £427,600) by the nations trading in the Elbe, the exchequer of Hanover was in the yearly receipt of about £45,000 from this source. Hamburg and Great Britain each paid more than a third of the redemption money.

STAËL, MADAME DE. ANNE LOUISE GERMAINE NECKER, BARONNE DE STAËL-HOLSTEIN (1766–1817), French novelist and miscellaneous writer, was born at Paris on the 22nd of April 1766. Her father was the famous financier Necker, her mother Suzanne Curchod, almost equally famous as the early love of Gibbon, as the wife of Necker himself, and as the mistress of one of the most popular salons of Paris. Between mother and daughter there was, however, little sympathy. Mme Necker, despite her talents, her beauty and her fondness for *philosophe* society, was strictly decorous, somewhat reserved, and disposed to carry out in her daughter's case the rigorous discipline of her own childhood. The future Mme de Staël was from her earliest years a romp, a coquette, and passionately desirous of prominence and attention. There seems moreover to have been a sort of rivalry between mother and daughter for the chief place in Necker's affections, and it is not probable that the daughter's love for her mother was increased by the consciousness of her own inferiority in personal charms. Mme Necker was of a most refined though somewhat lackadaisical style of beauty, while her daughter was a plain child and a plainer woman, whose sole attractions were large and striking eyes and a buxom figure. She was, however, a child of unusual intellectual power, and she began very early to write though not to publish. She is said to have written her father a letter on his famous *Compte-Rendu* and other matters when she was not fifteen, and to have injured her health by excessive study and intellectual excitement. But in reading all the accounts of Mme de Staël's life which come from herself or her intimate friends, it must be carefully remembered that she was the most distinguished and characteristic product of the period of *sensibilité*—the singular fashion of ultra-sentiment which required that both men and women, but especially women, should be always palpitating with excitement, steeped in melancholy, or dissolved in tears. Still, there is no doubt that her father's dismissal from the ministry, which followed the presentation of the *Compte*, and the consequent removal of the family from the busy life of Paris, were beneficial to her. During part of the next few years they resided at Coppet, her father's estate on the Lake of Geneva, which she herself made famous. But other parts were spent in travelling about, chiefly in the south of France. They returned to Paris, or at least to its neighbourhood, in 1785, and Mlle Necker resumed literary work of a miscellaneous kind, including a novel, *Sophie*, printed in 1786, and a tragedy, *Jeanne Grey*, published in 1790. It became, however, a question of marrying her. Her want of beauty was compensated by her fortune. But her parents are said to have objected to her marrying a Roman Catholic, which, in France, considerably limited her choice. There is a legend that William Pitt the younger thought of her; the somewhat notorious lover of Mlle de Lespinasse, Guibert, a cold-hearted coxcomb of some talent, certainly paid her addresses. But she finally married Eric Magnus, Baron of Staël-Holstein, who was first an attaché of the Swedish legation, and then minister. For a great heiress and a very ambitious girl the marriage scarcely seemed brilliant, for Staël had no fortune and no very great personal distinction. A singular series of negotiations, however, secured from the king of Sweden a promise of the ambassadorship for twelve years and a pension in case of its withdrawal, and the marriage took place on the 14th of January 1786. The husband was thirty-seven, the wife twenty. Mme de Staël was accused of extravagance, and latterly an amicable separation of goods had to be effected between the pair. But this was a mere legal formality, and on the whole the marriage seems to have met the views of both parties, neither of whom had any affection for the other. They had three children; there was no scandal between them; the baron obtained money and the lady obtained, as a guaranteed ambassadress of a foreign power of consideration, a much higher position at court and in society than she could have secured by marrying almost any Frenchman, without the inconveniences which might have been expected had she married a Frenchman superior to herself in rank. Mme de Staël was not a *persona grata* at court, but she seems to have played the part of ambassadress, as she played most parts, in a rather noisy and exaggerated manner, but not ill. Then in 1788 she appeared as an author under her own name (*Sophie* had been already published, but anonymously) with some *Lettres sur J. J. Rousseau*, a fervid panegyric showing a good deal of talent but no power of criticism. She was at this time, and indeed generally, enthusiastic for a mixture of Rousseauism and constitutionalism in politics. She exulted in the meeting of the states-general, and most of all when her father, after being driven to Brussels by a state intrigue, was once more recalled and triumphantly escorted into Paris. Every one knows what followed. Her first child, a boy, was born the week before Necker finally left France in unpopularity and disgrace; and the increasing disturbances of the Revolution made her privileges as ambassadress very important safeguards. She visited Coppet once or twice, but for the most part in the early days of the revolutionary period she was in Paris taking an interest and, as she thought, a part in the councils and efforts of the Moderates. At last, the day before the September massacres, she fled, befriended by Manuel and Tallien. Her own account of her escape is, as usual, so florid that it provokes the question whether she was really in any danger. Directly it does not seem that she was; but she had generously strained the privileges of the embassy to protect some threatened friends, and this was a serious matter.

She betook herself to Coppet, and there gathered round her a considerable number of friends and fellow-refugees, the beginning of the quasi-court which at intervals during the next five-and-twenty years made the place so famous. In 1793, however, she made a visit of some length to England, and established herself at Mickleham in Surrey as the centre of the Moderate Liberal emigrants—Talleyrand, Narbonne, Jaucourt and others. There was not a little scandal about her relations with Narbonne; and this Mickleham sojourn (the details of which are known from, among other sources, the letters of Fanny Burney) has never been altogether satisfactorily accounted for. In the summer she returned to Coppet and wrote a pamphlet (*Réflexions sur le procès de la reine*) on the queen's execution. The next year her mother died, and the fall of Robespierre opened the way back to Paris. M de Staël (whose mission had been in abeyance and himself in Holland for three years) was accredited to the French republic by the regent of Sweden; his wife reopened her salon and for a time was conspicuous in the motley and eccentric society of the Directory. She also published several small works, the chief being an essay *De l'Influence des passions* (1796), and another *De la Littérature considérée dans ses rapports avec les institutions sociales* (1800). It was during these years that Mme de Staël was of chief political importance. Narbonne's place had been supplied by Benjamin Constant, whom she first met at Coppet in 1794, and who had a very great influence over her, as in return she had over him. Both personal and political reasons threw her into opposition to Bonaparte. Her own preference for a moderate republic or a constitutional monarchy was quite sincere, and, even if it had not been so, her own character and Napoleon's were too much alike in some points to admit of their getting on together. For some years, however, she was able to alternate between Coppet and Paris without difficulty, though not without knowing that the First Consul disliked her. In 1797 she, as above mentioned, separated formally from her husband. In 1799 he was recalled by the king of Sweden, and in 1802 he died, duly attended by her. Besides the eldest son Auguste Louis, they had two other children—a son Albert, and a daughter Albertine, who afterwards became the duchesse de Broglie.

The exact date of the beginning of what Mme de Staël's admirers call her duel with Napoleon is not easy to determine. Judging from the title of her book *Dix années d'exil*, it should be put at 1804; judging from the time at which it became pretty clear that the first man in France and she who wished to be the first woman in France were not likely to get on together, it might be put several years earlier. The whole question of this duel, however, requires consideration from the point of view of common sense. It displeased Napoleon no doubt that Mme de Staël should show herself recalcitrant to his influence. But it probably pleased Mme de Staël to quite an equal degree that Napoleon should apparently put forth his power to crush her and fail. Both personages had a curious touch of *charlatanerie*. If Mme de Staël had really desired to take up her parable against Napoleon seriously, she need only have established herself in England at the peace of Amiens. But she lingered on at Coppet, constantly hankering after Paris, and acknowledging the hankering quite honestly. In 1802 she published the first of her really noteworthy books, the novel of *Delphine*, in which the "femme incomprise" was in a manner introduced to French literature, and in which she herself and not a few of her intimates appeared in transparent disguise. In the autumn of 1803 she returned to Paris. Whether, if she had not displayed such extraordinary anxiety not to be exiled, Napoleon would have exiled her remains a question; but, as she began at once appealing to all sorts of persons to protect her, he seems to have thought it better that she should not be protected. She was directed not to reside within forty leagues of Paris, and after considerable delay she determined to go to Germany. She journeyed, in company with Constant, by Metz and Frankfort to Weimar, and arrived there in December. There she stayed during the winter and then went to Berlin, where she made the acquaintance of August Wilhelm Schlegel, who afterwards became one of her intimates at Coppet. Thence she travelled to Vienna, where, in April, the news of her father's dangerous illness and shortly of his death (April 8) reached her. She returned to Coppet, and found herself its wealthy and independent mistress, but her sorrow for her father was deep and certainly sincere. She spent the summer at the château with a brilliant company; in the autumn she journeyed to Italy accompanied by Schlegel and Sismondi, and there gathered the materials of her most famous work, *Corinne*. She returned in the summer of 1805, and spent nearly a year in writing *Corinne*; in 1806 she broke the decree of exile and lived for a time undisturbed near Paris. In 1807 *Corinne*, the first aesthetic romance not written in German, appeared. It is in fact, what it was described as being at the time of its appearance, "a picturesque tour couched in the form of a novel." The publication was taken as a reminder of her existence, and the police of the empire sent her back to Coppet. She stayed there as usual for the summer, and then set out once more for Germany, visiting Mainz, Frankfort, Berlin and Vienna. She was again at Coppet in the summer of 1808 (in which year Constant broke with her, subsequently marrying a German lady) and set to work at her book, *De l'Allemagne*. It took her nearly the whole of the next two years, during which she did not travel much or far from her own house. She had bought property in America and thought of moving thither, but chance or fatality made her determine to publish *De l'Allemagne* in Paris. The submission to censorship which this entailed was sufficiently inconsistent and she wrote to the emperor one of the unfortunate letters, at once undignified and provoking, of which she had the secret. A man less tyrannical or less mean-spirited than Napoleon would of course have let her alone, but Napoleon was Napoleon, and she perfectly well knew him. The reply to her letter was the condemnation of the whole edition of her book (ten thousand copies) as "not French," and her own exile, not as before to a certain distance from Paris, but from France altogether. The act was unquestionably one of odious tyranny, but it is impossible not to ask why she had put herself within reach of it when her fortune enabled her to reside anywhere and to publish what she pleased. She retired once more to Coppet, where she was not at first interfered with, and she found consolation in a young officer of Swiss origin named Rocca, twenty-three years her junior, whom she married privately in 1811. The intimacy of their relations could escape no one at Coppet, but the fact of the marriage (which seems to have been happy enough) was not certainly known till after her death.

The operations of the imperial police in regard to Mme de Staël are rather obscure. She was at first left undisturbed, but by degrees the château itself became taboo, and her visitors found themselves punished heavily. Mathieu de Montmorency and Mme Récamier were exiled for the crime of seeing her; and she at last began to think of doing what she ought to have done years before and withdrawing herself entirely from Napoleon's sphere. In the complete subjection of the Continent which preceded the Russian War this was not so easy as it would have been earlier, and she remained at home during the winter of 1811, writing and planning. On the 23rd of May she left Coppet almost secretly, and journeyed by Bern, Innsbruck and Salzburg to Vienna. There she obtained an Austrian passport to the frontier, and after some fears and trouble, receiving a Russian passport in Galicia, she at last escaped from the dungeon of Napoleonic Europe.

She journeyed slowly through Russia and Finland to Sweden, making some stay at St Petersburg, spent the winter in Stockholm, and then set out for England. Here she received a brilliant reception and was much lionized during the season of 1813. She published *De l'Allemagne* in the autumn, was saddened by the death of her second son Albert, who had entered the Swedish army and fell in a duel brought on by gambling, undertook her *Considérations sur la révolution française*, and when Louis XVIII. had been restored returned to Paris. She was in Paris when the news of Napoleon's landing arrived and at once fled to Coppet, but a singular story, much discussed, is current of her having approved Napoleon's return. There is no direct evidence of it, but the conduct of her close ally Constant may be quoted in its support, and it is certain that she had no affection for the Bourbons. In October, after Waterloo, she set out for Italy, not only for the advantage of her own health but for that of her second husband, Rocca, who was dying of consumption. Her daughter married Duke Victor de Broglie on the 20th of February 1816, at Pisa, and became the wife and mother of French statesmen of distinction. The whole family returned to Coppet in June, and Byron now frequently visited Mme de Staël there. Despite her increasing ill-health she returned to Paris for the winter of 1816–1817, and her salon was much frequented. But she had already become confined to her room, if not to her bed. She died on the 14th of July, and Rocca survived her little more than six months.

Mme de Staël occupies a singular position in French literature. The men of her own time exalted her to the skies, and the most extravagant estimates of her (as "the greatest woman in literary history," as the "foundress of the romantic movement," as representing "ideas," while her contemporary Chateaubriand only represented words, colours, and images, and so forth) are to be found in minor histories of literature. On the other hand, it is acknowledged that she was soon very little read. No other writer of such eminence is so rarely quoted; none is so entirely destitute of the tribute of new and splendid editions. The abundant documents in the hands of her descendants, the families of Broglie and Haussonville, have indeed furnished material for books and papers, but these are almost wholly on the social aspect of Mme de Staël, not on her literary merit. Nor, when the life and works are examined is the neglect without excuse. Her books are seen to be in large part merely clever reflections of other people's views or views current at the time. The sentimentality of her sentiment and the florid magniloquence of her style equally disgust the reader. But to state this alone would be in the highest degree unfair. Mme de Staël's faults are great; her style is of an age, not for all time; her ideas are mostly second-hand and frequently superficial. But nothing save a very great talent could have shown itself so receptive. Take away her assiduous frequentation of society, from the later *philosophe* coteries to the age of Byron—take away the influence of Constant and Schlegel and her other literary friends—and probably little of her will remain. But to have caught from all sides in this manner the floating notions of society and of individuals, to reflect them with such vigour and clearness, is not anybody's task. Her two best books, *Corinne* and *De l'Allemagne*, are in all probability almost wholly unoriginal, a little sentiment in the first and a little constitutionalism in the second being all that she can claim. But *Corinne* is still a very remarkable exposition of a certain kind of aestheticism, while *De l'Allemagne* is still perhaps the most remarkable account of one country, by a native and inhabitant of another, which exists in literature.

Baron Auguste de Staël (d. 1827) edited the complete works of his mother in seventeen volumes (Paris, 1820–1821), with a notice by Mme Necker de Saussure, and the edition was afterwards republished in a compacter form, and, supplemented by some *Œuvres inédites*, is still obtainable in three volumes, large 8vo (Didot). The *Considérations* and the *Dix années d'exil* had been published after Mme de Staël's death. Some *Lettres inédites* to H. Meister were published in 1903. There is no recent reissue of the whole, and the minor works have not been reprinted, but *Corinne*, *Delphine* and *De l'Allemagne* are easily accessible in cheap and separate forms. Of separate works on Mme de Staël, or rather on Coppet and its society, besides those of MM Caro and Othenin d'Haussonville, may be mentioned the capital work of A. Sorel in the *Grands écrivains français*. In English there are biographies by A. Stevens (London, 1880), and Lady Blennerhasset (1889). (G. SA.)

STAFF (O. Eng. *staef*, cf. Du. *staf*, Ger. *Stab*, &c.; Icel. *stafr* meant also a written letter, and O. Eng. *stafas*, the letters of the alphabet; "stave," one of the thin pieces of wood of which a cask is made, is a doublet), a long stick or pole, used either as an aid in walking, as a weapon as in the old quarter-staff (*q.v.*) or as a symbol of dignity and office, *e.g.* the pastoral staff (*q.v.*). Further the word is applied to the pole on which a flag is hoisted and to various measuring surveying instruments. Probably from the early use of the word for the letters of the alphabet, "staff" and its doublet "stave" came to be used of a line, verse or stanza, and in musical notation (*q.v.*) of the horizontal lines on which notes are placed to indicate the pitch. A particular use, perhaps derived from the sense of an aid or help, is that of a body of assistants, particularly military.

The *military staff* organization of to-day, with its subdivision and specialization, is a modern product. Although generals have always provided themselves with aides-de-camp and orderlies, the only official corresponding to a modern staff officer in a 16th or 17th century army was the "sergeant-major-general" or "major-general," in whom was vested the responsibility of forming the army in battle array and also the command of the foot. In those days armies, large and small, were arrayed in deep formations and, occupying but a narrow front both in camp and in battle, were easily manageable by one man and his messengers. A little later, however, we find a "quarter-master-general" and his assistants charged with the duties of selecting camps, reconnoitring the country and collecting information generally. The quartermaster-general himself was sometimes used, as Marlborough used Cadogan (*q.v.*), not only as chief-of-staff and as quartermaster-general in the strict sense, but also as the general's authorized representative with detachments, advanced guards, &c. But there was no subdivision of functions in the modern sense. A staff was a group of officers attached temporarily to headquarters and available for any mission which the commander thought fit to give them, and in the highly centralized armies of those days these missions (as regards junior officers) were practically limited to orderly work and reconnaissance, especially topographical reconnaissance. Subordinate generals had aides-de-camp only. Apart, then, from the "adjutants" or personal staffs (amongst whom must be reckoned the commander-in-chief's secretary, generally a civilian), the staff in the field in Frederick the Great's day was the quartermaster-general's staff, and it was chiefly concerned, both in peace and war, with military engineering duties. In the Seven Years' War Frederick's Q.M.G. staff[1] comprised two to six officers, usually engineers, and by 1806 the quartermaster-general had practically monopolized engineering and scientific appointments at headquarters. Summer the staff officers devoted to surveying and topographical reconnaissance; winter to the codification of the information obtained. None of them were employed or trained with troops, although Frederick the Great sometimes made the quartermaster-general's officers at Berlin do duty with the guards.

With the French Revolution, however, the organization of the staff gradually modified itself to suit the new conditions of warfare. The size of armies necessitated subdivision and separate staffs for the subordinate leaders, their mobility reduced the importance of minute topographical reconnaissance, and the necessity of communicating between the several groups of an army produced an increased demand for orderly officers. But naturally a fully developed staff system did not spring to life immediately. Only by degrees were generals evolved who could handle large and mobile armies, and the highly gifted army leaders who in time appeared, Napoleon of course above all, scarcely needed a general staff. Napoleon had a chief of staff, Marshal Berthier, who bore the old title of "major-general," but Berthier was practically a chief clerk, a man of extraordinary aptitude for business. Berthier's staff was distinctly a mobile war office, and the great captain who needed not advice, but obedience, was wont to despatch his orders by a crowd of subalterns. The principal contribution, therefore, made by Napoleon to the development of staff organization was the thorough establishment of the principle of corps and divisional autonomy. Corps and divisions to be self-contained required, and they were furnished with, their own staffs. The old type of "quartermaster," whose "castrametation" and engineering science had been essential in the days of rigid indivisible armies, disappeared and gave way to a type of staff officer whose duty was to translate his chief's general instructions (other than those delivered in the field by the gallopers of the personal staff) into orders for the various subordinate commanders. The general staff officer's functions as strategical assistant to his chief were non-existent. This system worked satisfactorily in the main while Berthier was at the head of the central office, somewhat less satisfactorily in the Waterloo campaign when Marshal Soult occupied his place, and worst of all it worked in various wars of the 19th century in which the self-contained great general was not forthcoming. The general staff became a mere bureau, divorced from the army. Thus on the French side in 1870 Marshal Bazaine so far distrusted his general staff that he forbade it to appear on the battlefield, and worked the army almost wholly by means of his personal staff. Thus the latter, the mere mouthpiece of the marshal, issued sketchy strategical orders for movements, and so reduced the rate of marching of the army to five or six miles a day; while the former, kept in the dark by the commander-in-chief, issued either no orders at all or orders that had no reference to the real condition of affairs and the marshal's intentions. The army at large distrusted both staffs equally.

The Prussian general staff was as different from this staff of bureaucrats and amateurs as day from night. Even before 1806 Massenbach (*q.v.*) had added the preparation of strategical plans to the work of the quartermaster-general's staff, obtaining thus at the expense of the adjutant-general's side the powers of a general staff in the modern sense. That he was incapable of using these powers is shown by the mournful history of Jena. But another quartermaster-general in the war of 1806, Scharnhorst (*q.v.*), took up his work and in a very different spirit. In Scharnhorst's first instructions of 1808 it was laid down that an *accurate* knowledge of troops and a *general* knowledge of country were essential to a staff officer who was to be practised in exercises with troops and also in surveying. Scharnhorst, moreover, distributed general staff officers in peace to the provincial commands. The business-like habits which he instilled into his pupils, and their close touch with commanders and troops, began a tradition of efficient and accurate staff work in the field, work in which the previous Prussian staff (and indeed all contemporary staffs except Napoleon's) had failed. Thus it was that although the battle of Gravelotte-Saint-Privat was fought on the German side by over 200,000 men and in two or three distinct phases with little central direction, and, moreover, was not finished until after dark, Moltke had in his hands at dawn next morning a complete account of the events of the battle, and of the losses and condition of the troops of each corps. This was the fruit not only of methodical training in the theory of staff duties but of constant practice with troops in field manœuvres.

Another very important feature of the Scharnhorst system was the periodical return of all general staff officers to regimental duty. This indeed has often been considered the keynote of efficiency. It did not at first meet with universal approval, but, like so many other military institutions in Prussia, financial considerations helped to ensure its retention until its intrinsic merits were proved in war. Just as the army was kept at a low peace effective and augmented on mobilization from a numerous reserve, so the staffs were small in peace, but as many officers as possible were passed through them so as to form a staff reserve within the regimental strength of the army.

But above all, the circulation of staff officers made it possible to educate the regimental officer in the approved doctrines of strategy and tactics. "Unity of doctrine" meant that instead of the complicated instructions hitherto issued for any operation, a brief note or even a hint was sufficient. In an army with a "doctrine" all ranks from general to subaltern speak the same language and use the same term in the same sense. There must always be shades of interpretation, varying with the individual officer, as was notably the case in all that Prince Frederick Charles and Blumenthal did in execution of Moltke's "directives" in 1866 and 1870. But the general lines of action in such an army are thoroughly fixed.

A further consequence of the new conception of staff work was an enormous increase in the "discretionary" powers of all officers. If there is to be one and only one doctrine, that doctrine must be comprehensive and elastic, and education in it must consist chiefly in applying the general principle to the specific case. Thence it was not a long step to the notion that an officer could disregard a superior's orders if the situation on which they were based was wrongly conceived or had changed in the meantime. For the test of such independent action is that the "inferior should be conscientiously satisfied that the superior, in his place, would act as he himself proposes to do," and this, of course, is the very purpose of unity of doctrine. The exercise of initiative was peculiarly useful and necessary in the case of the staff officer. He could not only disobey superior orders, but give orders in the name of superior authority. He was better able than any other person to say, not only what action the Field Service Regulations laid down generally for such problems as that in hand, but also what solution his own general, possessing better information than the regimental officers, would adopt if present. The latitude in this respect accorded to German staff officers as well as to German commanders, is a most striking phenomenon of the war of 1870 (*e.g.* Colonel von Caprivi before Vionville and Colonel von der Esch at Wörth).

The result of unity of doctrine, then, was that a properly qualified officer could act as a substitute for his superior, and that the orders which he gave in that capacity were obeyed even by officers higher in rank than the originator of the order. This principle, owing to the peculiar circumstances of the

[1] The "general staff" was simply the list of general officers.

German army, was carried to an extreme in the case of the chiefs of staff. Moltke himself was a chief of staff, the king, although more experienced than any officer in his army, deliberately accepting Moltke's guidance and assuming the responsibility for the orders that Moltke issued in his name. On several occasions the king indeed formed a different conclusion from Moltke's and gave his orders accordingly, but these were exceptions. The effect of this, however, is not to deprive or to relieve the actual commander from the responsibility for the results of his action, whether that action was suggested by his own brain or by his staff officer's. Such an arrangement depends moreover on mutual confidence. The self-sufficing great commander does not need a Moltke, an average general is wholly ruled by his mentor; and between these two extremes the influence of the chief of staff varies according to circumstances and the character of the general. In the German armies of 1870, for example, the chief staff officer was in one case the reflector of his chief's views, in another he was the real army commander, in a third the characters of the two men were opposed in an almost paralysing equilibrium, while in a fourth the staff officer's business was to soothe and encourage an angry and disheartened commander and at the same time to "keep him straight."

This delicate adjustment is a necessary result of the absorption—inevitable under modern conditions of war—of strategical and even tactical functions by the general staff. The serious risks of disunion within the headquarters—and 1870 proves that even "unity of doctrine" does not altogether eliminate this disunion—has to be faced, and is best insured against by the selection of officers appropriate to each other. The imagination and technique of Hess supplemented the vigorous commonsense of Radetzky; Blücher, with the single supreme military quality of character, could leave all the brain-work to his Gneisenau. But usually, unless other than purely military considerations determine the selection of the general-in-chief (in which case he can make the best soldier in the army—irrespective of seniority—his adviser), smooth and efficient working is best secured when the general and his chief of staff possess the same military qualities in different balance, each compensating the other's weaknesses and deriving strength from the other's good qualities. In the Prussian account of the war of 1859 Moltke writes:—

"Great captains have no need of counsel. They study the questions which arise, and decide them, and their *entourage* has only to execute their decisions. But such generals are stars of the first magnitude, who scarcely appear once in a century. In the great majority of cases the leader of the army cannot do without advice. This advice may be the outcome of the deliberations of a small number of qualified men. But within this small number one and only one opinion must prevail. The organization of the military hierarchy must ensure subordination even in thought, and give the right and duty of presenting a single opinion for the examination of the general-in-chief to one man, and one only. He will be appointed, not by seniority, but by reason of the confidence he inspires. The general-in-chief will always have, as compared with his adviser, the infinitely weightier merit of having assumed the responsibility of executing what he advises."

Thus the chief of the general staff is defined in the British Field Service Regulations as the general's "responsible adviser on all matters affecting military operations, through whom he exercises his functions of command and by whom all orders issued by him will be signed."

Staff Duties in the Field.—The manifold duties essential and incidental to commanding and administering an army, which the general performs, as above defined, through his staff, are in the British service classified broadly into three headings—general staff work, adjutant-general's work and quartermaster-general's work. The immediate head of the general staff, and (if the general delegates the duty) the supervising authority over the other staffs, is the chief of the general staff. The link between the army and the inspector-general or controller of its lines of communication is the quartermaster-general. All details required for insertion in general staff (*i.e.* "operation") orders that come within the adjutant-general's or the quartermaster-general's branch are drafted by those branches in accordance with the general lines laid down by the general staff, and inserted in the orders issued by the general staff. "Routine" orders are drafted and issued by the other staffs themselves.

a. General Staff Duties (*Operations*).—The study of proposed operations; the framing, issue and despatch of the operation orders; plans for movements to the points of concentration and for strategic deployment; general allotment of areas for quarters; measures of security; intercommunication; reconnaissance; acquisition, collation and distribution of information as to the enemy and the country; flags of truce and correspondence with the enemy; censorship; provision, distribution and revision of maps; reports and despatches relating to operations; furnishing of the adjutant-general's and quartermaster-general's staffs with information as to the situation and probable requirements of the troops, and receiving from these branches such information as affects the operations in prospect.

b. Adjutant-General's Staff (*Personnel*).—Discipline; application of military law, martial law and international law, both to the army and to the civil population of occupied areas; questions of promotion, appointments of officers, pay, rewards, enlistments; chaplain's services; casualties and invaliding; medical and sanitary services; organization of new corps and drafts; prisoners of war; police; routine and interior economy; ceremonial.

c. Quartermaster-General's Staff (*Matériel*).—Distribution of camps and quarters within allotted areas; supplies, equipment and clothing (except medical stores); transport by land and sea; railway administration; remounts; veterinary service; postal service.

The work of the lower staffs—divisions and brigades—is similarly subdivided as far as necessary. There are, moreover, the small personal staffs (aides-de-camp) of the army and divisional commanders. The work of the latter is not of course as important as it was under the old system, and is partly of a social character, partly orderly work. The headquarters staff of an army of six infantry and one cavalry divisions consists of: *Personal Staff*, 5 officers; *General Staff*, chief and 10 other officers; *Adjutant-General's Staff*, adjutant-general and 4 officers; *Quartermaster-General's Staff*, quartermaster-general and 3 officers; attached in various capacities, 28 officers. 232 non-commissioned officers and men are employed in the work of headquarters as clerks, printers, cooks, servants, &c. The staff of a division consists of: *Personal*, 2 aides-de-camp; *General*, 3 or 4 officers; *Adjutant-General's*, 1 officer; *Quartermaster-General's*, 1 officer; attached, 8 officers; rank and file attached, 64–80 men. A brigade staff consists of one general staff officer for operations, a brigade major for administration, and one aide-de-camp: attached, 1 officer; rank and file, 33–45.

Staff Duties in Peace.—In modern conditions peace is normal and war exceptional; moreover, as between European nations, the need of a swift decision of a quarrel is so urgent that immediately after mobilization and concentration, if not indeed during these preliminaries, the decisive action of the war may be begun. Success in such a war is the consequence of national spirit in the first place and of the peace training of all ranks in the second. The direction and supervision of the latter is the principal duty of a staff in time of peace, and therefore the specialization of staff functions, referred to above, in the three branches of operations, *personnel* and *matériel*, is as well marked in peace as in war. The two latter branches, which are concerned with the maintenance rather than the use of an army, are necessarily quite as fully occupied in peace as in war, for the life of the army is uninterrupted. But the "general staff" branch would not have enough work to justify a separate existence, were it not for the fact that on the battlefield nothing can be reaped that has not been sown. Nowadays, as the decisive battle immediately follows the concentration of the armies, the crop that is expected to be reaped must be sown in peace time. To this end the modern general staff in peace not only has an existence apart from the routine and supply staffs, but, as in war, occupies the first place in importance. In Great Britain, perhaps more than in any other state, the functions of training and administration are very sharply differentiated. Each commander-in-chief of a large group of garrisons has under him not only a brigadier-general at the head of the general staff, but a major-general "in charge of administration," who in all questions of administration is the *alter ego* of the commander-in-chief. The latter is thus free to devote himself to the training of his troops, which he carries out through the medium of his general staff officers. Only those administrative questions that involve important decisions come before him, the whole of the routine work being carried out by the general in charge of administration in his own office and on his own responsibility.

In the War Office, the general staff work, under the Chief of the Imperial General Staff, is classified into three main heads, for each of which there is a general officer as "director." These are: (*a*) *Military Operations*, in which all strategical matters connected with imperial defence and operations overseas are studied. (*b*) *Staff Duties*, which organizes and co-ordinates the whole of the general staff work, and also deals with questions of war organization. (*c*) *Military Training*, which supervises the Staff College and other educational institutions and also the Officers' Training Corps, and controls and in some cases conducts the professional examinations of officers and candidates for commissions. Under this branch is placed the section which arranges questions of home defence.

The administrative work is divided between the three departments of the *Adjutant-General* (peace organization, mobilization arrangements, record offices and routine orders, medals, regimental distinctions, titles, &c.; certain artillery and engineer services; and the large and exceedingly important service of personnel, discipline, recruiting, casualties, drafts and reliefs); the *Quartermaster-General* (movements and quartering, barracks, railway administration, mobilization arrangements for rail and sea transportation; remounts and registration of horses for service in war; Army Service Corps work, including horse and mechanical transport, vehicles, &c.; training of administrative *personnel*; veterinary duties; provision and maintenance of supplies, clothing and stores); the *Master-General of the Ordnance* (armaments and weapons of all kinds, ammunition and explosive stores, military engineering and fortifications, barrack and building construction). Besides these three departments there are the civil departments of the *Civil Member of the Army Council*, under whom, on account of its citizen character, has been placed the administration of the Territorial Force, and who has further all duties connected with war department lands, roads, &c.; and of the *Finance Minister*, which works out the annual estimates, examines financial proposals such as contracts, administers the Army Pay Department, and deals with accounts and audits.

Directly under the Army Council is the department of the Inspector-General of the Forces, whose duties are to review and report upon the training and efficiency of all troops under the home government, the state of stores, remounts, &c., with regard to war requirements, and the condition of fortifications.

STAFFA (Norse for staff, column, or pillar island), an island of the Inner Hebrides, Argyllshire, Scotland, 54 m. W. of Oban by steamer, about 7 m. from the nearest point of Mull, and 6 m. N. by E. of Iona. It lies almost due north and south, is $\frac{3}{4}$ m. long by about $\frac{1}{3}$ m. wide, is $1\frac{1}{2}$ m. in circumference, has an area of 71 acres, and its highest point is 135 ft. above sea-level. In the north-east it shelves to a shore, but otherwise the coast is rugged and much indented, numerous caves having been carved out by rain, stream and ocean. There is enough grass on the surface to feed a few cattle, and the island contains a spring, but it is uninhabited. During the tourist season it is visited every week-day by steamer from Oban. The island is of volcanic origin, a fragment of an ancient stream of lava. In section the isle is seen to possess a threefold character: there is first a basement of tufa, from which rise, secondly, colonnades of basalt in pillars forming the faces and walls of the principal caves, and these in turn are overlaid, thirdly, by a mass of amorphous basalt. Only the chief caves have been named. On the south-east coast is the Clam-shell or Scallop Cave. It is 30 ft. high, about 18 ft. wide at the entrance, and some 130 ft. long, and on one side of it the ridges of basalt stand out like the ribs of a ship. Near this cave is the rock of Buachaille ("The Herdsman," from a supposed likeness to a shepherd's cap), a pile of columns, fully seen only at low water. On the south-west shore are the Boat Cave and Mackinnon's or the Cormorants' Cave. Fingal's Cave is, however, the most famous of all. It was discovered in 1772 by Sir Joseph Banks, who visited Staffa on his expedition to Iceland. The grotto, situated in the southern face of the isle, is 227 ft. long, 42 ft. wide, 66 ft. high and 25 ft. deep at ebb. On its western side the pillars are 36 ft. high, on its east 18 ft. high. From its mouth to its extremity a pavement of broken pillars runs up one side. The cave is the haunt of seals and sea birds. In suitable atmospheric conditions its beauty is unique. The play of colour is exquisite, the basalt combining every tint of warm red, brown and rich maroon; sea-weeds and lichens paint the cave green and gold; while the lime that has filtered through has crusted the pillars here and there a pure snow-white. From the sombre roof of smooth rock or broken pillars hang yellow, crimson and white stalactites. The floor of the cave is the green sea, out of which the columns rise on either side with a regularity so perfect as to suggest the hand of man rather than the work of Nature. The murmur of the sea won for the cave a Gaelic name meaning "the Cave of Music." At times of storm the compressed air, as it rushes out, produces a sound as of thunder. When the sea is very smooth visitors may be rowed directly into the cave, but the more usual landing-place is near the Clam-shell Cave, where the columns have been worn down until they form a kind of terrace running all the way to Fingal's Cave. The Wishing Chair is formed out of a column that has broken short. From the Causeway a ladder affords access to the summit of Staffa.

STAFFORD (Family). This famous English house was founded in England by Robert, a younger brother of Ralf de Tosny (Toeni), of a noble Norman house, who was standard-bearer of the duchy. Robert received, like his elder brother, at the Conquest a great fief which extended into seven counties and became known as Robert de Stafford from his residence at Stafford Castle. The military service due from the fief was no less than sixty knights, as is proved by his grandson Robert's return in 1166. With this Robert's son the male line became extinct, and his sister's husband, Hervey Bagot, one of his knightly tenants, succeeded to the fief in her right (1194): their descendant Edmund de Stafford (that surname having been assumed) was summoned as a baron in 1299. His son, Ralph, a warrior like his father, attained fame in the French wars. He conducted the brilliant defence of Aiguillon against the host of France, fought at Crecy and in the siege of Calais. Chosen a Knight of the Garter at the foundation of the order, he was further created earl of Stafford in 1351.

His son Hugh, who succeeded as 2nd earl in 1372, served in the French wars. From 1376 he became prominent in politics, probably through his marriage to a daughter of the earl of Warwick, being one of the four lords on the committee in the Good Parliament, and also serving on the committee that controlled Richard II., 1378–1380. He was friendly, however, with that king, and was with him on his Scottish expedition in 1385. He died next year on pilgrimage at Rhodes. The marriage of his son, Thomas, the 3rd earl, in 1392 to the daughter and eventual heiress of Thomas, duke of Buckingham (son of Edward III.), by a coheiress of the great house of Bohun, proved a decisive turning-point in the history of the Staffords; for, although he died childless, this great lady, styled "countess of Stafford, Buckingham, Hereford and Northampton" in her will, married in 1398 his brother Edmund, the 5th earl, who obtained, in addition to her great possessions, her ancestors' office of lord high constable in 1403, but was slain the same year at Shrewsbury, commanding the van of the king's host. Their son, Humphrey (1402–1460), the first Stafford duke of Buckingham, was placed by his descent and his possessions in the front rank of the English nobility.

The Staffords fell from their pinnacle of greatness, which had aroused the jealousy of the Crown, by the attainder of Henry the 2nd duke in 1483, but were completely restored for the time, on the triumph of Henry VII. in 1486, when Edward, the 3rd duke (1478–1521), regained the title and estates. Under Henry VIII. his great position, fortified by his relationship to the Percys, Howards and Nevilles, made him a natural leader of the old nobility, while his recovery of the ancestral office of lord high constable in 1509 increased his prestige. He had not sufficient force of character to take an active part in politics, but the king's easily roused suspicions were excited by private accusations in 1521, and, after a nominal trial by his peers, he was beheaded on the 17th of May 1521, a subsequent act (1523) confirming his attainder. His fate, even under such a king, made a great sensation, exciting sympathy at home, and moving the emperor Charles V. to say that a butcher's dog (Wolsey) had pulled down the noblest buck in England. It is noteworthy that the 2nd and 3rd dukes were both beheaded, while the 1st duke fell in the Wars of the Roses.

Henry (1501–1563), the son of the last duke, was granted by the Crown some of his father's manors for his support, and, espousing the Protestant cause (though married to a daughter of Margaret, countess of Salisbury and sister of Cardinal Pole), was restored in blood on Edward VI.'s accession and declared Lord Stafford, as a new creation, by act of parliament. His second surviving son, Thomas, eventually assumed the royal arms, on the ground of his lofty descent, sailed from Dieppe with two ships in April 1557, landed at Scarborough, seized the castle, and proclaimed himself protector. He was captured and executed for high treason. His father's new barony, in 1637, passed to a cadet in humble circumstances, who was called on, as a pauper, to surrender it to the king, which he did (illegally, it is now held) in 1639. The king thereupon bestowed it on Mary Stafford (the heir general of the line) and her husband, William Howard, in whose descendants it is now vested. Roger, who had surrendered the title, died in 1640, the last heir male, apparently, of the main line of this historic house.

Of the junior lines the most important was that known as Stafford of Hooke (Co. Dorset), which had branched off from the parent stem at a very early date. Sir John Stafford of this line married his kinswoman, a daughter of the 1st earl of Stafford. From their younger son, Ralf, descended the Staffords of Grafton and other families; the elder, who fought in the French wars, was grandfather of John (Stafford), archbishop of Canterbury. This prelate came to the front under Henry VI., becoming treasurer (1422), bishop of Bath and Wells (1425), and lord chancellor (1432–1450). Archbishop from 1443 to his death in 1452, he steered an even course between parties as a moderate man and useful official. His elder brother obtained Hooke by marriage, and left two sons, of whom the younger was grandfather of Humphrey Stafford, who succeeded to Hooke, fought for Edward IV. at Towton, and was summoned as Lord Stafford of Southwick in July 1461, and was advanced to the earldom of Devon on the 7th of May 1469, after the execution of the Courtenay earl, which he is said to have intrigued for. Failing to support the earl of Pembroke against the rebels a few months later, he was responsible for their victory, for which he was arrested and beheaded (Aug. 17). With him ended the Staffords of Hooke.

Sir Humphrey Stafford of Grafton (of their cadet line) was an active supporter of Richard III., and was executed for high treason by Henry VII. in 1485. From him descended Sir Edward Stafford (whose mother was a daughter of Henry, Lord Stafford), an Elizabethan diplomatist, who was appointed resident ambassador to France in 1583, a post which he held with success to 1590, sitting afterwards in parliament for Stafford, and dying in 1605. His brother William (1554–1612) was concerned in some obscure plots under Elizabeth.

Another offshoot from the main line was that of the Staffords of Clifton (Co. Stafford), founded by Sir Richard, younger brother of the 1st earl of Stafford, who was closely associated with him in French warfare and negotiation, fought, like him, at Crecy, and acted as seneschal of Gascony (1361–1362). Clifton came to him in marriage with a Camville heiress, and he was summoned as a baron in 1371. His eldest surviving son, Edmund (1344–1419), a churchman, became bishop of Exeter in 1395, and was lord chancellor from 1396 to 1399. He lost the office on Henry IV.'s accession, but held it again from 1401 to 1403. He then devoted himself to his diocese till his death in 1419. His patronage of learning is commemorated by Exeter College, Oxford. The male line of the Staffords of Clifton ended about 1445.

Of younger sons of the main line who attained peerage rank Sir Hugh Stafford, K.G., a son of the 2nd earl, was summoned as a baron from 1411 to 1413 (probably in right of his wife, a Bourchier heiress), but died childless in 1420. John, a son of the 1st duke of Buckingham, received the garter and an earldom of Wiltshire (1470), which became extinct with his son in 1499, but was revived in 1510 for Henry Stafford, K. G., a son of the 2nd duke, who, however, died childless in 1523.

The Staffords made illustrious marriages from the day of the 1st earl; a son of the 1st duke married the mother of Henry VII. The badge of the family was "the Stafford knot," at one time as famous as "the ragged staff" of the earls of Warwick.

See Dugdale, *Baronage* (1675), vol. i.; G. E. C(okayne), *Complete Peerage*; Wrottesley, *History of the Family of Bagot* (1908) and *Crecy and Calais* (1898). The important Stafford MSS. in Lord Bagot's possession are calendared in the 4th Report on Historical MSS., and the Salt Arch. Soc.'s collections for the history of Staffordshire are valuable for early records. Harcourt's *His Grace the Steward and the Trial of Peers* (1907) should also be consulted. The bishop of Exeter's Register was edited by Hingeston-Randolph in 1886. *Papers relating to the two Baronies of Stafford* (1807), and Campbell's *The Stafford Peerage* (1818) are useful for the pedigree, and there are collections for a history of the family in Add. MSS. (Brit. Mus.) 14,409; 19,150. (J. H. R.)

STAFFORD, EARLS AND MARQUESSES OF. The earldom of Stafford, created in 1351, was held at first by the family of Stafford (see above). In 1521 it became extinct, and in September 1640 Sir William Howard (1614–1680), a son of Thomas Howard, earl of Arundel and Surrey, having three years previously married Mary (d. 1694), sister and heiress of Henry Stafford, 5th Baron Stafford, was created Baron Stafford and two months later viscount of Stafford. Accused by Titus Oates of participating in the popish plots, he was found guilty, and was beheaded on the 29th of December 1680, his titles being forfeited.

His son, Henry Stafford Howard (1658–1719), who, but for his father's attainder, would have inherited the barony and the viscounty, was created earl of Stafford in 1688, his mother being created countess of Stafford at the same time; he was succeeded by his nephew William (*c.* 1690–1734). When John Paul, the 4th earl (1700–1762), died, the earldom became extinct, but the title to the barony, which was under attainder, fell into abeyance.

The 4th earl's sister Mary (d. 1765) married Francis Plowden (d. 1712), and in 1824 their descendant, Sir George William Jerningham, Bart. (1771–1851), of Costessy Park, Norfolk, obtained a reversal of his ancestor's attainder and was recognized as Baron Stafford. The barony is still held by the Jerninghams.

In 1758 Granville Leveson-Gower (1721–1803) was created marquess of Stafford. He was the son of John Leveson-Gower (d. 1754), who was created Viscount Trentham and Earl Gower in 1746. The public positions held by him included that of lord privy seal, which he filled from 1755 to 1757, and again from 1784 to 1794; of master of the horse; of lord chamberlain of the royal household; and of lord president of the council, which he held from 1767 to 1769 and in 1783–1784. This wealthy and influential nobleman, who was the last survivor of the associates of the duke of Bedford, the "Bloomsbury gang," died at Trentham Hall, in Staffordshire, on the 26th of October 1803. His son and successor, George Granville Leveson-Gower, was created duke of Sutherland in 1833. A younger son was Granville Leveson-Gower, who was created Earl Granville in 1833. The title of marquess of Stafford is now borne by the eldest son of the duke of Sutherland.

STAFFORD, a market town, municipal and parliamentary borough, and the county town of Staffordshire, England, on the river Sow, a western tributary of the Trent. Pop. (1901), 20,895. It is an important junction on the main line of the London & North-Western railway, by which it is $133\frac{1}{2}$ m. N.W. from London. Branches of this company diverge to Wolverhampton and Birmingham, and to Walsall; a joint line of the North-Western and Great Western companies to Shrewsbury and Welshpool; the Great Northern serves the town from the eastern counties, and the North Staffordshire runs north through the Potteries district. The town, while largely modernized, contains a number of picturesque half-timbered houses. The church of St Mary, a fine cruciform building having a transitional Norman nave, and Early English and Decorated in other parts, was formerly collegiate, its canons having mention in Domesday, though the complete foundation is attributed to King John. It contains a memorial to the famous angler, Izaak Walton, born at Stafford in 1593. The older church of St Chad contains good Norman details, but is chiefly a reconstruction. It formerly provided sanctuary. There are county council buildings, a shire hall and a borough hall. The grammar school is an ancient foundation enlarged in 1550 by Edward VI. The county technical institution is in Stafford. A museum, consisting principally of the collections of Clement Wragge, and called by his name, contains a specially fine series of fossils. The William Salt library, presented to the borough in 1872 after the death of the collector, has a large collection of books and MSS., deeds and pictures relating to the county. Charitable institutions include a general infirmary, county asylum, and the Coton Hill intitution for the insane. The burgesses of Stafford had formerly common rights over a considerable tract known as Coton Field and Stone Flat; the first is now divided into allotments and the second is a recreation ground. The staple trade is the manufacture of boots and shoes; there are ironworks, and salt is prepared from brine wells in the neighbourhood. These also supply baths. The parliamentary borough was extended in 1885, when the representation was reduced from two members to one. The town is governed by a mayor, 8 aldermen and 24 councillors. Area, 1084 acres.

In the beautiful well-wooded neighbourhood an interesting site is that of Stafford Castle, on a hill commanding a wide prospect. The existing ruin is that of an unfinished mansion dating from 1810, which replaced an old stronghold. Beyond it is an early encampment, Bury Ring.

Stafford (*Stadford, Staffort, Stafforde*) is said to have originally been called Betheney from Berthelin, a hermit who lived here. The first authentic mention of it is in the Anglo-Saxon Chronicle, where it is stated that Aethelflead, lady of the Mercians, in 913 built a fort at Stafford. It was a place of considerable importance in later Anglo-Saxon times, and the evidence of coins shows that a mint then existed here. Stafford is described as a borough in Domesday Book, and at the time of the survey it was the chief place in the county though many of the houses were "wasted." The king received all the dues, two-thirds coming to him as king, the other third as earl of Stafford. From the Domesday Survey it appears that the Conqueror took certain land out of the manor of Chelsea in order to erect a castle at Stafford; this was destroyed in the wars of the 17th century. A charter from John in 1206 constituted Stafford a free borough. In 1399 the government was by bailiffs. In 1501 it was ordered that two bailiffs should be elected annually out of a council of twenty-five burgesses. Charters were granted by Edward VI. in 1551 and by James I. in 1605, the latter incorporating it under the title of the mayor and burgesses of the borough of Stafford: owing to irregularities in elections, another almost similar charter was given by George IV., under which the town was governed until 1835. In Elizabeth's reign Stafford was in a depressed condition owing partly to the decay of the cap manufacture which formerly had been considerable. Speed (d. 1629) states that Lichfield is "more large" than Stafford: in the middle of the 18th century the town had "greatly encreased of late by their manufacture of cloth:" about the same time the shoe trade began. Two fairs, to be held on St Matthew's day and on the 4th of December, were granted in 1261 and 1685 respectively, and are still kept up. There are now eight annual fairs in all.

STAFFORDSHIRE, a midland county of England, bounded N.E. by Derbyshire, E. by that county and Leicestershire, S.E. by Warwickshire, S. by Worcestershire, S.W. by Shropshire and N.W. by Cheshire. The area is 1171·2 sq. m. The county includes the valley of the Trent from its source to the point at which it becomes navigable, Burton-upon-Trent. It rises in the extreme north of the county, and follows a southerly course, turning eastward and finally north-eastward through the centre of the county. Its tributaries on the left bank follow a course roughly parallel with it; the chief are the Blythe and the Dove, which receives the Churnet from the west, and forms the county boundary with Derbyshire. The country between Trent, Churnet and Dove is undulating and beautiful; the hills rise to some 1800 ft. on the Derbyshire border in Axe Edge near Buxton, and continue by Mow Cop or Congleton Edge along the Cheshire border to the coal-bearing hills above the Potteries district. Dovedale, the name applied to a portion of the upper valley of the Dove (*q.v.*), attracts many visitors on account of its beauty, and is in favour with anglers for its trout-fishing. South of the Trent, about the middle of the county, an elevated area is known as Cannock Chase, formerly a royal preserve, now a wealthy coalfield, and the high ground, generally exceeding 500 ft., continues south to surround the great manufacturing district of south Staffordshire (the Black Country), and to merge into the Clent and Lickey Hills of Worcestershire. A small area in the north-west drains to the Weaver, and so to the Mersey, and from the west and south-west the Severn receives some small feeders and itself touches the county in the extreme south-west. The only considerable sheet of water is Aqualate Mere, in the grounds of the mansion of that name near Newport in Shropshire.

Geology.—The Pennine folding gently plicates the northern of two Carboniferous tracts interrupting the Midland Triassic plateau in Staffordshire, but affects the unconformable Trias less. It isolates the Pottery and smaller coalfields mainly in synclines, but elevates the western margin of the former anticlinally. A prolongation arches the South Staffordshire Coal Measures, with minor saddles disclosing Silurian inliers, intermediate formations being absent there. Faults depressing the Trias bound the southern coalfield on both sides, the northern Carboniferous westward. At Walsall Upper Llandovery Sandstone with *Stricklandinia lens* and Barr (Woolhope) Limestone (*Illaenus barriensis*) underlie Wenlock Shales, succeeded, as at Wren's Nest and Dudley, by Wenlock Limestone in two beds, honeycombed with old lime-workings and famous for trilobites. At Sedgley there follow Lower Ludlow Shales, Sedgley (Aymestry) Limestone (*Pentamerus knighti*) and some Upper Ludlow Shale. Carboniferous Limestone, with gently-sloping hills and deep valleys, enters the northern region on the east. It contains brachiopods and corals of the *Dibunophyllum* zone, with lead and copper, once worked at Ecton. Marine Pendleside (Yoredale) Shales, with thin limestones and higher sandstones, ascend around a central syncline and the northern margins of the coalfields into the Millstone Grit, whose four grits in massive escarpments, only the "First" and "Third" persisting westward, alternate with shales. The Pottery Coalfield, the centre of pottery manufacture, though local clays now furnish only coarse ware and the "saggars" in which pottery is baked, includes 8000 ft. of Coal Measures, chiefly shales, clays and sandstones, diminishing southward. The Lower and Middle Measures (5000 ft.) contain the principal coals, about forty, with comparatively barren strata (1000 ft.) preceding the Winpenny, Bullhurst, Cockshead, Bambury, Ten-foot, and higher coals associated with "clayband" ironstones. The neighbouring Cheadle Coalfield comprises the lower 2000 ft., with the Crabtree, Woodhead and Dilhorne coals; two other little coalfields comprise only the lowest strata. The South Staffordshire coalfield has 500–1000 ft. of equivalent measures, with the Bottom, Fireclay, New Mine, Heathen, the composite Tenyard and other coals, besides ironstones to which the Black Country originally owed its hardware industry. Plants (*Lepidodendron, Neuropteris heterophylla*), fresh-water shells (*Carbonicola acuta, C. robusta*) and fishes are characteristic fossils; but the roof of the North Staffordshire Crabtree Coal (Lower Measures) and several higher bands yield marine goniatites, &c. Shales, pottery-clays and "blackband" ironstones with thin *Spirorbis*-limestones, Entomostraca and *Anthracomya phillipsi* (Blackband Series), succeed in the Pottery Coalfield. Then follow red brick-clays with ashy grits (Etruria Marls); white sandstones with *Pecopteris arborescens* (Newcastle-under-Lyme Series); red sandstones and clays with *Spirorbis*-limestones (Keele Series); paralleled in South Staffordshire respectively by Red Coal Measure Clays, Halesowen Sandstone, and beds like the Keele Series. Around this the Triassic sequence ascends outwards through Bunter (Pebble-Beds between Mottled Sandstones), Keuper Sandstone and Waterstones into Keuper Marl, which, containing gypsum and brine-springs, covers the central plateau, the sandstones emerging marginally and axially. The Pebble-Beds rise in Cannock Chase, and fringe the northern coalfields. Rhaetic outliers on Needwood Forest contain *Axinus cloacinus*. The Rowley and other doleritic sills and dikes invade the southern, one dike the Pottery Coalfield and the Trias.

Glacial drift partly conceals the rocks. Irish Sea ice, entering on the west, left boulder-clay with stratified sands, and mingled with local material, Lake District and Scotch erratics, and shells swept from the sea-bed. It threw down a gravelly moraine before the marginal hills of the Pottery Coalfield, and concentrated countless boulders between Rugeley and Enville. Barred northward by this ice, the Arenig glacier carried Welsh erratics across South Staffordshire to Birmingham. North Sea ice with Cretaceous and Jurassic débris reached east Staffordshire.

Agriculture.—Nearly four-fifths of the total area of the county is under cultivation, and of this more than two-thirds is in permanent pasture, cattle being largely kept, and especially cows for the supply of milk to the towns. Like most of the midland counties, Staffordshire is well wooded. The acreage under corn crops is steadily diminishing, and wheat, which formerly was the principal corn crop, is now superseded in this respect by oats, which occupies over one-half of the corn acreage, little more being under wheat than under barley. Turnips are grown on about half the acreage under green crops.

Manufactures.—The manufactures of Staffordshire are varied and important. Out of the three great coalfields in the north, south and centre (Cannock Chase), the two first have wholly distinct dependent industries. The southern industrial district is commonly known as the Black Country (*q.v.*); it is the principal seat in England of iron and steel manufacture in all its branches. It covers an area, between Birmingham and Wolverhampton, resembling one great town, and includes such famous centres as Walsall, Wednesbury, Dudley (in Staffordshire) and West Bromwich. The northern industrial district is called the Potteries (*q.v.*). Cheadle, east of the Potteries, is the centre of a smaller coalfield. Burton-upon-Trent is famous for its breweries. Chemical works are found in the Black Country, brick and tile works in the Black Country and at Tunstall, glassworks at Tutbury; there are also a considerable textile industry, as at Newcastle-under-Lyme, paper-mills in that town and at Tamworth, and manufactures of boots and shoes at Stafford and Stone.

Communications.—The main line of the London & North-Western railway runs from south-east to north-west by Tamworth, Lichfield (Trent Valley), Rugeley and Stafford. This company and the Great Western serve the towns of the Black Country by many branches from Birmingham, and jointly work the Stafford-Shrewsbury line. The London & North-Western has branches from Trent Valley to Burton-upon-Trent, and from Rugeley through the Cannock Chase coalfields. The North Staffordshire railway runs from Stafford and from Burton-upon-Trent northward through the Potteries, with a line from Uttoxeter through Leek to Macclesfield. The Manifold Valley light railway serves part of the Dovedale district. The west-and-north line of the Midland railway (Bristol-Derby) crosses the south-eastern part of the county from Birmingham by Tamworth and Burton, with a branch to Wolverhampton. The Great Northern, with a branch from its main line at Grantham, serves Uttoxeter, Burton and Stafford. A considerable amount of coal-transport takes place along canals, the Black Country especially being served by numerous branches. The principal canals are—the Grand Trunk, which follows the Trent over the greater part of

Information embodied from the Ordnance Survey, by permission of the Controller of H.M. Stationery Office. Emery Walker sc.

its course within the county, the Coventry, Birmingham and Fazeley, Daw End and Essington canals, connecting the Grand Trunk with Warwickshire, the Black Country and Cannock Chase; the Liverpool and Birmingham junction; the Staffordshire and Worcestershire, running from the Severn at Stourport by Wolverhampton and Penkridge to the Grand Junction near Stafford, and the Caldon canal running eastward from the Potteries into the Churnet Valley.

Population and Administration.—The area of the ancient county is 749,602 acres, with a population in 1891 of 1,083,424; and in 1901 of 1,234,506. The area of the administrative county is 744,984 acres. Staffordshire contains five hundreds, each having two divisions. The municipal boroughs are: in the southern industrial district, Smethwick (pop. 54,539), Walsall (86,430), Wednesbury (26,554), West Bromwich (65,175), Wolverhampton (94,187); in the northern industrial district, Newcastle-under-Lyme (19,914), and the several formerly separate boroughs amalgamated under the "Potteries Federation" Scheme (1908) under the name of Stoke-on-Trent (*q.v.*); elsewhere, Burton-upon-Trent (50,386), Lichfield (7902), Stafford (20,895), Tamworth (7271). Burton, Hanley, Smethwick, Walsall, West Bromwich and Wolverhampton are county boroughs; Lichfield is a city, and Stafford is the county town. The urban districts are—in the southern industrial district, Amblecote (3218), Bilston (24,034), Brierley Hill (12,042), Coseley (22,219), Darlaston (15,395), Handsworth (52,921), Heath Town or Wednesfield Heath (9441), Perry Bar (2348), Quarry Bank (6912), Rowley Regis (34,670), Sedgley (15,951), Short Heath (3531), Tettenhall (5337), Tipton (30,543), Wednesfield (4883), Willenhall (18,515); in the northern industrial district, Audley (13,683), Biddulph (6247), Fenton (22,742), Kidsgrove (4552), Smallthorne (6263), Tunstall (19,492), Wolstanton (24,975); elsewhere, Brownhills (15,252), Cannock (23,974), Leek (15,484), Rugeley (4447), Stone (5680), Uttoxeter (5133). Among other towns may be mentioned Abbots Bromley (1318), Brewood (2535), Cheadle (5186) and Eccleshall (3799). The county is in the Oxford circuit, and assizes are held at Stafford. It has one court of quarter sessions, and is divided into 23 petty sessional divisions. The boroughs of Hanley, Lichfield, Newcastle-under-Lyme, Walsall, West Bromwich and Wolverhampton have separate commissions of the peace and courts of quarter sessions, and those of Burslem, Burton, Longton, Stafford, Stoke-upon-Trent, Smethwick, Tamworth and Wednesbury have separate commissions of the peace only. The total number of civil parishes is 277. The county is almost wholly in the diocese of Lichfield, but has small parts in those of Worcester, Hereford, Southwell and Chester; it contains 348 ecclesiastical parishes or districts, wholly or in part. Staffordshire is divided into seven parliamentary divisions each returning one member—Burton, Handsworth, Kingswinford, Leek, Lichfield, North-West and West. The parliamentary borough of Wolverhampton returns a member for each of three divisions, and the boroughs of Hanley, Newcastle-under-Lyme, Stafford, Stoke-upon-Trent, Walsall, Wednesbury and West Bromwich each return one member.

History.—The district which is now Staffordshire was invaded in the 6th century by a tribe of Angles who settled about Tamworth, afterwards famous as a residence of the Mercian kings, and later made their way beyond Cannock Chase, through the passages afforded by the Sow valley in the north and Watling Street in the south. The district was frequently overrun by the Danes, who in 910 were defeated at Tettenhall, and again at Wednesfield, and it was after Edward the Elder had finally expelled the Northmen from Mercia that the land of the south Mercians was formed into a shire around the fortified burgh which he had made in 914 at Stafford. The county is first mentioned by name in the Anglo-Saxon Chronicle in 1016 when it was harried by Canute.

The resistance which Staffordshire opposed to the Conqueror was punished by ruthless harrying and confiscation, and the Domesday Survey supplies evidence of the depopulated and impoverished condition of the county, which at this period contained but 64 mills, whereas Dorset, a smaller county, contained 272. No Englishman was allowed to retain estates of any importance after the Conquest, and the chief lay proprietors at the time of the survey were Earl Roger of Montgomery; Earl Hugh of Chester; Henry de Ferrers, who held Burton and Tutbury castles; Robert de Stafford; William Fitz-Ansculf, afterwards created first Baron Dudley; Richard Forester; Rainald Bailgiol; Ralph Fitz Hubert and Nigel de Stafford. The Ferrers and Staffords long continued to play a leading part in Staffordshire history, and Turstin, who held Drayton under William Fitz Ansculf, was the ancestor of the Bassets of Drayton. At the time of the survey Burton was the only monastery in Staffordshire, but foundations of canons existed at Stafford, Wolverhampton, Tettenhall, Lichfield, Penkridge and Tamworth, while others at Hanbury, Stone, Strensall and Trentham had been either destroyed or absorbed before the Conquest. The five hundreds of Staffordshire have existed since the Domesday Survey, and the boundaries have remained practically unchanged. Edingale, however, was then included under Derbyshire, and Tirley under Shropshire, while Cheswardine, Chipnall and part of Bobbington, now in Shropshire, were assessed under Staffordshire. The hundreds of Offlow and Totmonslow had their names from sepulchral monuments of Saxon commanders. The shire court for Staffordshire was held at Stafford, and the assizes at Wolverhampton, Stafford and Lichfield, until by act of parliament of 1558 the assizes and sessions were fixed at Stafford, where they are still held.

In the 13th century Staffordshire formed the archdeaconry of Stafford, including the deaneries of Stafford, Newcastle, Alton and Leek, Tamworth and Tutbury, Lapley and Creigull. In 1535 the deanery of Newcastle was combined with that of Stone, the deaneries remaining otherwise unaltered until 1866, when they were increased to twenty. The archdeaconry of Stoke-on-Trent was formed in 1878, and in 1896 the deaneries were brought to their present number; the archdeaconry of Stafford comprising Handsworth, Himley, Lichfield, Penkridge, Rugeley, Stafford, Tamworth, Trysull, Tutbury, Walsall, Wednesbury, West Bromwich and Wolverhampton; the archdeaconry of Stoke-on-Trent comprising Alstonfield, Cheadle, Eccleshall, Hanley, Leek, Newcastle-under-Lyme, Stoke-on-Trent, Trentham and Uttoxeter.

In the wars of the reign of Henry III. most of the great families of Staffordshire, including the Bassets and the Ferrers, supported Simon de Montfort, and in 1263 Prince Edward ravaged all the lands of Earl Robert Ferrers in this county and destroyed Tutbury Castle. During the Wars of the Roses, Eccleshall was for a time the headquarters of Queen Margaret, and in 1459 the Lancastrians were defeated at Blore Heath. In the Civil War of the 17th century Staffordshire supported the parliamentary cause and was placed under Lord Brooke. Tamworth, Lichfield and Stafford, however, were garrisoned for Charles, and Lichfield Cathedral withstood a siege in 1643, in which year the Royalists were victorious at Hopton Heath, but lost their leader, the earl of Northampton. In 1745 the Young Pretender advanced as far as Leek in this county.

A large proportion of Staffordshire in Norman times was waste and uncultivated ground, but the moorlands of the north afforded excellent pasturage for sheep, and in the 14th century Wolverhampton was a staple town for wool. In the 13th century mines of coal and iron are mentioned at Walsall, and ironstone was procured at Sedgley and Eccleshall. In the 15th century both coal and iron were extensively worked. Thus in the 17th century the north of the county yielded coal, lead, copper, marble and millstones, while the rich meadows maintained great dairies; the woodlands of the south supplied timber, salt, black marble and alabaster; the clothing trade flourished about Tamworth, Burton, and Newcastle-under-Lyme; and hemp and flax were grown all over the county. The potteries are of remote origin, but were improved in the 17th century by two brothers, the Elers, from Amsterdam, who introduced the method of salt glazing, and in the 18th century they were rendered famous by the achievements of Josiah Wedgwood.

Staffordshire was represented by two members in the parliament of 1290, and in 1295 the borough of Stafford also returned two members. Lichfield was represented by two members in 1304, and Newcastle-under-Lyme in 1355. Tamworth returned two members in 1562. Under the Reform Act of 1832 the county returned four members in four divisions, and the boroughs of Stoke-on-Trent and Wolverhampton were represented by two members each, and Walsall by one member. Under the act of 1868 the county returned six members in three divisions and Wednesbury returned one member.

Antiquities.—Early British remains exist in various parts of the county; and a large number of barrows have been opened in which human bones, urns, fibulae, stone hammers, armlets, pins, pottery and other articles have been found. In the neighbourhood of Wetton, near Dovedale, on the site called Borough Holes, no fewer than twenty-three barrows were opened, and British ornaments have been found in Needwood Forest, the district between the lower Dove and the angle of the Trent to the south. Several Roman camps also remain, as at Knave's Castle on Watling Street, near Brownhills. The most noteworthy churches in the county are found in the large towns, and are described under their respective headings. Such are the beautiful cathedral of Lichfield, and the churches of Eccleshall, Leek, Penkridge St Mary's at Stafford, Tamworth, Tutbury, and St Peter's at Wolverhampton. Checkley, 4 m. south of Cheadle, shows good Norman and Early English details, and there are carved stones of pre-Norman date in the churchyard. Armitage, south-east of Rugeley, has a church showing good Norman work. Brewood church, 4 m. south-west of Penkridge, is Early English. This village gives name to an ancient forest. Audley church, north-west of Newcastle-under-Lyme, is a good example of Early Decorated work. Remains of ecclesiastical foundations are generally slight, but those of the Cistercian abbey of Croxden, north-west of Uttoxeter, are fine Early English, and at Ranton, west of Stafford, the Perpendicular tower and other portions of an Augustinian foundation remain. Among medieval domestic remains may be mentioned the castles of Stafford, Tamworth and Tutbury, with that of Chartley, north-east of Stafford, which dates from the 13th century. Here is also a timbered hall, in the park of which a breed of wild cattle is maintained. Beaudesert, south of Rugeley, is a fine Elizabethan mansion in a beautiful undulating demesne. In the south-west, near Stourbridge, are Enville, a Tudor mansion with grounds laid out by the poet Shenstone, and Stourton Castle, embodying portions of the 15th century, where Reginald, Cardinal Pole, was born in 1500. Among numerous modern seats may be named Ingestre, Ilam Hall, Alton Towers, Shugborough, Patteshull, Keele Hall, and Trentham.

See Robert Plot, *Natural History of Staffordshire* (Oxford, 1686); S. Erdeswick, *Survey of Staffordshire* (London, 1717; 4th ed., by T. Harwood, London, 1844); Stebbing Shaw, *History and Antiquities of Staffordshire*, &c., vol. i., ii., pt. i. (London, 1798–1801); William Pitt, *Topographical History of Staffordshire* (Newcastle-under-Lyme, 1817); Simeon Shaw, *History of the Staffordshire Potteries* (Hanley, 1829); Robert Garner, *Natural History of the County of Stafford* (London, 1844–1860); William Salt, Archaeological Society, *Collections for a History of Staffordshire* (1880), vol. i.; *Victoria County History; Staffordshire.*

STAG (O. Eng. *stagga*, a Norse word, cf. Icel. *steggr*, *steggi*, a male animal, cf. *Steggander*, a drake; it is usually referred to *stigan*, to climb, to mount, but this is doubtful), the common name of the male of many species of the deer tribe, but usually confined to the male of the red deer (*Cervus elaphus*), "buck" being used in other cases, as of the fallow-deer (see Deer and Pecora). In Stock Exchange slang the term is used of an operator who applies for a portion of a new security being issued, not with a view to holding it, but with the intention of immediate realization, at a profit if possible.

STAGE (Fr. *étage*; from Lat. *stare*, to stand), in architecture, an elevated floor, particularly the various storeys of a bell-tower, &c. The term is also applied to the plain parts of buttresses between cap and cap where they set back, or where they are divided by horizontal strings and panelling. It is used, too, by William of Worcester to describe the compartments of windows between transom and transom, in contradistinction to the word *bay*, which signifies a division between mullion and mullion (see Storey). From the sense of the floor or platform on which plays were acted the term came to signify both the theatre (*q.v.*) and the drama (*q.v.*). And from its etymological meaning of a station comes the sense of a place for rest on a journey, the distance between such places, &c.

STAHL, FRIEDRICH JULIUS (1802–1861), German ecclesiastical lawyer and politician, was born at Munich on the 16th of January 1802, of Jewish parentage. Although brought up strictly in the Jewish religion, he was allowed to attend the gymnasium, and, as a result of its influence, was at the age of nineteen baptized into the Lutheran Church. To this faith he clung with earnest devotion and persistence until his death. Having studied law at Würzburg, Heidelberg and Erlangen, Stahl, on taking the degree of *doctor juris*, established himself as *privatdozent* in Munich, was appointed (1832) ordinary professor of law at Würzburg, and in 1840 received the chair of ecclesiastical law and polity at Berlin. Here he immediately made his mark as an ecclesiastical lawyer, and was appointed a member of the first chamber of the synod. Elected in 1850 a member of the short-lived Erfurt parliament, he bitterly opposed the idea of German federation. Stahl early fell under the influence of Schelling, and at the latter's insistence, began in 1827 his great work: *Die Philosophie des Rechts nach geschichtlicher Ansicht* (an historical view of the philosophy of law), in which he bases all law and political science upon Christian revelation, denies rationalistic doctrines, and, as a deduction from this principle, maintains that a state church must be strictly confessional. This position he further elucidated in his *Der christliche Staat und sein Verhältniss zum Deismus und Judenthum* (The Christian State and its relation to Deism and Judaism; 1874). As Oberkirchenrath (synodal councillor) Stahl used all his influence to weaken the Evangelical Union (*i.e.* that compromise between the Calvinist and Lutheran doctrines which is the essence of the Prussian Evangelical Church) and to strengthen the influence of the Lutheran Church (cf. *Die Lutherische Kirche und die Union*, 1859). The Prussian minister von Bunsen attacked, while King Frederick William IV. supported, Stahl in his ecclesiastical policy, and the Prussian Evangelical Church would probably have been dissolved had not the regency of Prince William (afterwards the emperor William I.) supervened in 1858. Stahl's influence fell under the new régime, and, resigning his seat on the synod, he retired into private life and died at Brückenau on the 10th of August 1861.

See " Biographie von Stahl," in *Unsere Zeit*, vi. 419–447 (anonymous, but probably by Gneist); *Pernice, Savigny, Stahl* (anonymous; Berlin, 1862).

STAHL, GEORG ERNST (1660–1734), German chemist and physician, was born on the 21st of October 1660 at Anspach. Having graduated in medicine at Jena in 1683, he became court physician to the duke of Weimar in 1687. From 1694 to 1716 he held the chair of medicine at Halle, and was then appointed physician to the king of Prussia in Berlin, where he died on the 14th of May 1734. In chemistry he is chiefly known in connexion with his doctrine of phlogiston, the essentials of which, however, he owed to J. J. Becher; and he also propounded a view of fermentation which in some respects resembles that supported by Liebig a century and half later. In medicine he professed an animistic system, in opposition to the materialism of Hermann Boerhaave and Friedrich Hoffmann.

The most important of his numerous writings are *Zymotechnia fundamentalis sive fermentationis theoria generalis* (1697), which contains the phlogistic hypothesis; *Specimen Becherianum* (1702); *Experimenta, observationes, animadversiones . . . chymicae et physicae* (1731); *Theoria medica vera* (1707); *Ars sanandi cum expectatione* (1730).

STAINER, SIR JOHN (1840–1901), English composer and organist, was born at Southwark on the 6th of June 1840. He was the second son of the schoolmaster of the parish school of St Thomas's, Southwark, who was enough of a musician to teach his son the organ and the art of reading music, in which he was already proficient when, in 1847, he entered the choir of St Paul's Cathedral. He remained there till 1856, and often took the organ in emergencies; he held the post of organist of St Benet's and St Paul's, Upper Thames Street, during the last year of his choristership; and in 1856 was given the appointment of organist to St Michael's College, Tenbury, where his musical and general education benefited greatly from the intercourse with Sir Frederick Gore Ouseley. He was appointed to Magdalen College, Oxford, in 1860, and became university organist in the following year. While at Oxford he did much to bring the choir of Magdalen to a remarkable state of excellence; he took a keen interest in the foundation of various musical societies; and as a sign of his appreciation of the value of general culture, it is worth recording that he took the degree of B.A. in 1864, that of Mus. D. in 1865, and procured M.A. in 1867, being appointed a university examiner in music in the same year. In 1868 he was engaged frequently as solo organist at the Crystal Palace; and in 1872 was appointed organist of St Paul's, where he raised the standard of choral music to something very like perfection. He was professor of the organ in the National Training School of Music from 1876, and in 1881 succeeded his lifelong friend Sullivan as principal. In 1878 he was a juror at the Paris Exhibition, and was created Chevalier of the Légion d'Honneur. In 1882 he became inspector of music in training colleges. In 1888 he retired from the organistship of St Paul's owing to failing eyesight, and was knighted. In 1889 he succeeded Ouseley as professor of music in the university of Oxford, holding the post till 1899. Besides these official distinctions he received a great number of honorary degrees: he was vice-president of the Royal College of Organists, and president of the Plain-song and Medieval Music Society, the London Gregorian Association, and the Musical Association. His compositions include four oratorios: *Gideon* (1865), *The Daughter of Jairus* (Worcester, 1878), *St Mary Magdalen* (Gloucester, 1887), *Crucifixion* (London, 1887); forty-two anthems, some of them very elaborate; many hymn-tunes, organ pieces, madrigals, &c. His professorial lectures were of great value, and he made many contributions to the literature of music. He was a man of wide influence, with a remarkable faculty of organization, and his work in regard to the conditions of the musical profession was of considerable importance. His own music has many of the defects of his qualities, for his breadth of artistic views led him to admire and adopt many styles that are not always compatible with each other. He died while on a holiday at Verona on the 31st of March 1901.

STAINES, a market town in the Uxbridge parliamentary division of Middlesex, England, on the river Thames at the junction of the Colne, 19 m. W.S.W. of London on the London & South Western and Great Western railways. Pop. of urban district (1901), 6688. Breweries and mustard mills employ many hands. A rifle range for the Metropolitan Volunteers and others was opened in 1892. A British village was situated here at the crossing of the Thames on the main road from London to south-western Britain, and the crossing was certainly one of the earliest bridged. A grant of oaks from Windsor forest for the repair of the bridge is recorded in 1262. The existing bridge, from the designs of George Rennie, was opened in 1831, after three bridges had failed in the previous forty years. The name of Staines appears in the Domesday Survey, and it has been supposed that the town is so called from a stone which marks the limit of the former jurisdiction of the City of London over the lower Thames. This is still considered to be the boundary between the upper and lower Thames. In the immediate neighbourhood, though included in the parish of Egham, Surrey, is Runnimede Island, where King John signed the Magna Carta.

STAIR, JAMES DALRYMPLE, 1st VISCOUNT (1619–1695), Scottish lawyer and statesman, was born in May 1619, at Drummurchie in Ayrshire. He was descended from a family for several generations inclined to the principles of the Reformation, and had ancestors both on the father's and the mother's side amongst the Lollards of Kyle. His father, James Dalrymple, laird of the small estate of Stair in Kyle, died when he was an infant; his mother, Janet Kennedy of Knockdaw, is described as " a woman of excellent spirit," who took care to have him well educated. From the grammar school at Mauchline he went, in 1633, to the university of Glasgow, where he graduated in arts on the 26th of July, 1637. Next year he went to Edinburgh, probably with the intention of studying law, but the troubles of the times, then approaching a crisis, led him to change his course, and we next find him serving in the earl of Glencairn's regiment in the War of the Covenant. What part he took in it is not certainly known, but he was in command of a troop when recalled in 1641 to compete for a regency (as a tutorship or professorship was then called) in the university of Glasgow. He was elected in March. Mathematics, logic, ethics and politics were the chief subjects of his lectures, and a notebook on logic by one of his students has been preserved. His activity and skill in matters of college business were praised by his colleagues, who numbered amongst them some of the leading Covenanting divines, and his zeal in teaching was gratefully acknowledged by his students. After nearly seven years' service he resigned his regency, and removed to Edinburgh, where he was admitted to the bar on the 17th of February 1648. This step had probably been rendered easier by his marriage, four years before, to Margaret Ross, co-heiress of Balneil in Wigtown. Stair's practice at the bar does not appear to have been large; his talents lay rather in the direction of learning and business than of oratory or advocacy. His reputation and the confidence reposed in him were shown by his appointment in 1649 as secretary to the commission sent to the Hague to treat with Charles II. by the parliament of Scotland. The negotiation having been broken off through the unwillingness of the young king to accept the terms of the Covenanters, Stair was again sent in the following year to Breda, where the failure of Montrose's expedition forced Charles to change his attitude and to return to Scotland as the covenanted king. Stair had preceded him, and met him on his landing in Aberdeenshire, probably carrying with him the news of the execution of Montrose, which he had witnessed.

During the Commonwealth Stair continued to practise at the bar; but like most of his brethren he refused in 1654 to take the oath of allegiance to the Commonwealth. Three years later, on the death of Lord Balcomie, Stair was appointed one of the commissioners for the administration of justice in Scotland, on the recommendation of Monk. His appointment to the bench on the 1st of July 1657, by Monk, was confirmed by Cromwell on the 26th. Stair's association with the English judges at this time must have enlarged his acquaintance with English law, as his travels had extended his knowledge of the civil law and the modern European systems which followed it. He thus acquired a singular advantage when he came to write on law, regarding it from a cosmopolitan, or international, rather than a merely local or national point of view. His actual discharge of judicial duty at this time was short, for after the death of Cromwell the courts in Scotland were shut—a new commission issued in 1660 not having taken effect, it being uncertain in whose name the commission ought to run. It was during this period that Stair became intimate with Monk, who is said to have been advised by him when he left Scotland to call a full and free parliament. Soon after the Restoration Stair went to London, where he was received with favour by Charles, knighted, and included in the new nomination of judges in the court of session on the 13th of February 1661. He was also put on various important commissions, busied himself with local and agricultural affairs, and, like most of the Scottish judges of this and the following century, acted with zest and credit the part of a good country gentleman.

In 1662 he was one of the judges who refused to take the declaration that the national covenant and the solemn league and covenant were unlawful oaths, and, forestalling the deposition which had been threatened as the penalty of continued non-compliance, he placed his resignation in the king's hands. The king, however, summoned him to London, and allowed him to take the declaration under an implied reservation. The next five years of Stair's life were comparatively uneventful, but in 1669 a family calamity, the exact facts of which will probably never be ascertained, overtook him. His daughter Janet, who had been betrothed to Lord Rutherfurd, was married to Dunbar of Baldoon, and some tragic incident occurred on the wedding night, from the effects of which she never recovered. As the traditions vary on the central fact, whether it was the bride who stabbed her husband, or the husband who stabbed the bride, no credence can be given to the mass of superstitions and spiteful slander which surrounded it, principally levelled at Lady Stair.[1] In 1670 Stair served as one of the Scottish commissioners who went to London to treat of the Union; but the project, not seriously pressed by Charles and his ministers, broke down through a claim on the part of the Scots to what was deemed an excessive representation in the British parliament. In January 1671 Stair was appointed president of the court of session. In the following year, and again in 1673, he was returned to parliament for Wigtownshire, and took part in the important legislation of those years in the department of private law. During the bad time of Lauderdale's government Stair used his influence in the privy council and with Lauderdale to mitigate the severity of the orders passed against ecclesiastical offenders, but for the most part he abstained from attending a board whose policy he could not approve. In 1679 he went to London to defend the court against charges of partiality and injustice which had been made against it, and was thanked by his brethren for his success. When, in the following year, the duke of York came to Scotland Stair distinguished himself by a bold speech, in which he congratulated the duke on his coming amongst a nation which was entirely Protestant. This speech can have been little relished, and the duke was henceforth his implacable enemy. His influence prevented Stair from being made chancellor in 1681, on the death of the duke of Rothes.

The parliament of this year, in which Stair again sat, was memorable for two statutes, one in private and the other in public law. The former, relating to the testing of deeds, was drawn by Stair, and is sometimes called by his name. The other was the infamous Test Act, probably the worst of the many measures devised at this period with the object of fettering the conscience by oaths. Stair also had a minor share in the form which this law finally took, but it was confined to the insertion of a definition of "the Protestant religion"; by this he hoped to make the test harmless, but his expectation was disappointed. Yet, self-contradictory and absurd as it was, the Test Act was at once rigidly enforced. Argyll, who declared he took it only in so far as it was consistent with itself and the Protestant religion, was tried and condemned for treason and narrowly saved his life by escaping from Edinburgh Castle the day before that fixed for his execution. Stair, dreading a similar fate, went to London to seek a personal interview with the king, who had more than once befriended him, perhaps remembering his services in Holland; but the duke of York intercepted his access to the royal ear, and when he returned to Scotland he found a new commission of judges issued, from which his name was omitted. He retired to his wife's estate in Galloway, and occupied himself with preparing for the press his great work, *The Institutions of the Law of Scotland*, which he published in the autumn of 1681, with a dedication to the king.

He was not, however, allowed to pursue his legal studies in peaceful retirement. His wife was charged with attending conventicles, his factor and tenants severely fined, and he was himself not safe from prosecution at any moment. A fierce dispute arose between Claverhouse and Stair's son, John, master of Stair, relative to the regality of Glenluce; and, both having appealed to the privy council, Claverhouse, as might have been expected, was absolved from all the charges brought against him and the master was deprived of the regality. Stair had still powerful friends, but his opponents were more powerful, and he received advice to quit the country. He repaired to Holland in October 1684, and took up his residence, along with his wife and some of his younger children, at Leiden. While there he published the *Decisions of the Court of Session between 1666 and 1671*, of which he had kept a daily record, and a small treatise on natural philosophy, entitled *Physiologia nova experimentalis*.

In his absence a prosecution for treason was raised against

[1] Sir Walter Scott took the plot of his *Bride of Lammermoor* from this incident, but he disclaimed any intention of making Sir William Ashton a portrait of Lord Stair.

him and others of the exiles by Sir G. Mackenzie, the lord advocate. He was charged with accession to the rebellion of 1679, the Rye House plot, and the expedition of Argyll. With the first two he had no connexion; with Argyll's unfortunate attempt he had no doubt sympathized, but the only proof of his complicity was slight, and was obtained by torture. The proceedings against him were never brought to an issue, having been continued by successive adjournments until 1687, when they were dropped. The cause of their abandonment was the appointment of his son, the master of Stair, who had made his peace with James II., as lord advocate in room of Mackenzie, who was dismissed from office for refusing to relax the penal laws against the Roman Catholics. The master only held office as lord advocate for a year, when he was "degraded to be justice clerk"—the king and his advisers finding him not a fit tool for their purpose. Stair remained in Holland till the following year, when he returned under happier auspices in the suite of William of Orange. William, who had made his acquaintance through the pensionary Fagel, was ever afterwards the firm friend of Stair and his family. The master was made lord advocate; and, on the murder of Lockhart of Carnwath in the following year, Stair was again placed at the head of the court of session. An unscrupulous opposition, headed by Montgomery of Skelmorlie; who coveted the office of secretary for Scotland, and Lord Ross, who aimed at the presidency of the court, sprang up in the Scottish parliament; and an anonymous pamphleteer, perhaps Montgomery himself or Ferguson the Plotter, attacked Stair in a pamphlet entitled *The Late Proceedings of the Parliament of Scotland Stated and Vindicated*. He defended himself by publishing an *Apology*, which, in the opinion of impartial judges, was a complete vindication.

Shortly after its issue he was created Viscount Stair (1690). He had now reached the summit of his prosperity, and the few years which remained of his old age were saddened by private and public cares. In 1692 he lost his wife, the faithful partner of his good and evil fortune for nearly fifty years. The massacre of the Macdonalds of Glencoe (Feb. 13, 1692), which has marked his son, the master of Stair, with a stain which his great services to the state cannot efface—for he was undoubtedly the principal adviser of William in that treacherous and cruel deed, as a signal way of repressing rebellion in the Highlands—was used as an opportunity by his adversaries of renewing their attack on the old president. His own share in the crime was remote; it was alleged that he had as a privy councillor declined to receive Glencoe's oath of allegiance, though tendered, on the technical ground that it was emitted after the day fixed, but even this was not clearly proved. But some share of the odium which attached to his son was naturally reflected on him. Other grounds of complaint were not difficult to make up, which found willing supporters in the opposition members of parliament. A disappointed suitor brought in a bill in 1693 complaining of his partiality. He was also accused of domineering over the other judges and of favouring the clients of his sons. Two bills were introduced without naming him but really aimed at him—one to disqualify peers from being judges and the other to confer on the Crown a power to appoint temporary presidents of the court. The complaint against him was remitted to a committee, which, after full inquiry, completely exculpated him; and the two bills, whose incompetency he demonstrated in an able paper addressed to the commission and parliament, were allowed to drop. He was also one of a parliamentary commission which prepared a report on the regulation of the judicatures, afterwards made the basis of a statute in 1695 supplementary to that of 1672, and forming the foundation of the judicial procedure in the Scottish courts for many years. On the 29th of November 1695 Stair, who had been for some time in failing health, died in Edinburgh, and was buried in the church of St Giles.

In 1695 there was published in London a small volume with the title *A Vindication of the Divine Perfections, Illustrating the Glory of God in them by Reason and Revelation, methodically digested—By a Person of Honour*. It was edited by the two Nonconformist divines, William Bates and John Howe, who had been in exile in Holland along with Stair, and is undoubtedly his work. Perhaps it had been a sketch of the "Inquiry Concerning Natural Theology" which he had contemplated writing in 1681. It is of no value as a theological work, for Stair was no more a theologian than he was a man of science, but it is of interest as showing the serious bent of his thoughts and the genuine piety of his character.

Stair's great legal work, *The Institutions of the Law of Scotland deduced from its Originals, and collated with the Civil, Canon and Feudal Laws and with the Customs of Neighbouring Nations*, affords evidence of the advantage he had enjoyed from his philosophical training, his foreign travels and his intercourse with Continental jurists as well as English lawyers. Unfortunately for its permanent fame and use, much of the law elucidated in it has now become antiquated through the decay of the feudal part of Scottish law and the large introduction of English law, especially in the departments of commercial law and equity.

The *Physiologia* was favourably noticed by Boyle, and is interesting as showing the activity of mind of the exiled judge, who returned to the studies of his youth with fresh zest when physical science was approaching its new birth. But he was not able to emancipate himself from formulae which had cramped the education of his generation, and had not caught the light which Newton spread at this very time by the communication of his *Principia* to the Royal Society of London.

Stair was fortunate in his descendants. "The family of Dalrymple," observes Sir Walter Scott, "produced within two centuries as many men of talent, civil and military, of literary, political and professional eminence, as any house in Scotland." His five sons were all remarkable in their professions. John, master of Stair (1648–1707), who was created 1st earl of Stair in 1703, an able lawyer and politician, who is, however, principally remembered for his part in the massacre of Glencoe, is dealt with above. Sir James Dalrymple of Borthwick, created a baronet in 1698, was one of the principal clerks of session, and a very thorough and accurate historical antiquary. Sir Hew Dalrymple of North Berwick (1652–1737) succeeded his father as president, and was reckoned one of the best lawyers and speakers of his time; he, too, was created a baronet in 1698. Thomas Dalrymple became physician to Queen Anne. Sir David Dalrymple of Hailes (d. 1721), who was created a baronet in 1700, was lord advocate under Anne and George I.; and his grandson was the famous judge and historian, Lord Hailes (*q.v.*).

Stair's grandson, John, 2nd earl (1673–1747), who rose to be a field-marshal, gained equal credit in war and diplomacy. He was ambassador in Paris (1715–1720), and, besides seeing service under Marlborough, was commander-in-chief of the British forces on the Continent in 1742, showing great gallantry at the battle of Dettingen. He had no son, and in 1707 had selected his nephew John (1720–1789) as heir to the title; but through a decision of the House of Lords in 1748 he only became 5th earl, after his cousin James and James's son had succeeded as 3rd and 4th earls. John's son, the 6th earl, died without issue, and a cousin again succeeded as 7th earl, his two sons becoming 8th and 9th earls. The 8th earl (1771–1853) was a general in the army, and keeper of the great seal of Scotland. The 9th earl's son and grandson succeeded as 10th and 11th earls.

For a fuller account of the life of Stair, see J. Murray Graham, *Annals of the Viscount and First and Second Earls of Stair* (1875); A. J. G. Mackay, *Memoir of Sir James Dalrymple, First Viscount Stair* (1875); and Sir R. Douglas, *Peerage of Scotland*, new ed., by Sir J. B. Paul.

STAIR (O. Eng. *staéger*, step, from *stigan*, to climb, cf. Ger. *steigen*; the root is also seen in "stile" and "stirrup"), in architecture, the term (Fr. *escalier*) given to a series of steps rising one above the other, either in one straight line or with returns, or round a newel, or open well-hole, either square, rectangular, circular or elliptical. A series of continuous steps is called a "flight." The ordinary staircase of two flights with landing between is known as a "pair"; "two pair back" therefore would be the room at the back on the second floor; in houses where the space occupied by the staircase is very limited there is no landing, but the stairs wind round the corner post or newel, and are known as "winders."

The steps of a stair consist of "tread" and "riser," the respective dimensions of which vary according to the importance of the staircase and the space which has been given to it; in external flights or stairs, such as those at Persepolis, the tread is so wide and the riser so small in height as to allow of a horse ascending, and generally in garden terraces there is the same slight rise. For the stairs of a palace or municipal building, 14 in. tread and 5 in. riser would be required, but as a rule 12 in. tread and 6 in. riser is adopted. In the stone staircase in the palace at Cnossus in Crete, the treads were 18 in. and the risers $5\frac{1}{2}$ in. In ordinary houses 9 in. or 10 in. is generally given for the tread, and $6\frac{1}{2}$ in. to 7 in. for the riser. In the stairs leading to lofts, and in yachts or steamers, the ascent is much steeper, having sometimes 10 in. rise and 5 in. tread. The series of stairs provided to ascend from one floor to another when enclosed with walls is known as a staircase (*q.v.*). Unenclosed flights of steps placed in front of a building are known by the French term *perron* (*q.v.*), usually applied to a structure like the horseshoe staircase of the palace at Fontainebleau, the stairs of which are carried on a support independent of the main wall of the palace. From this point of view the great return flight of steps at Persepolis might be looked upon as a staircase, because on one side the steps are all embedded in the main wall of the platform.

Belonging to the same type are the great flights of steps which led to the successive stages of the Ziggurats or Assyrian stage towers; those in front of the Propylaea, leading to the Acropolis at Athens; the stairs leading to the Propylaea (150 ft. in width) at Baalbek; others in Palmyra; and generally all the Roman temples. In medieval times should be included the great flights of steps which stood in front of the cathedrals of Europe, some of which, as those at Le Puy in France, Ste Gudule at Brussels, the cathedral at Erfurt in Germany, S. Miniato at Florence in Italy, and others, still exist, not having yet been buried by the gradual raising of the ground-level in great towns; also the immense flights of steps in Rome, leading up to the Trinita del Monte and the Capitol, and those found in all towns built on hills, when an architectural composition has guided their plan.

In Egyptian architecture inclined planes took the place of stairs, as in the sloping corridors of the Great Pyramid, the descent leading to the temple of the Sphinx, and the approaches to the two temples of Deir el-Bahri, one of them the oldest temple found. Inclined planes were also provided in front of some of the Greek temples, where the steps of the stylobate were of great height; similar contrivances were adopted by the Mahommedans in Egypt to ascend the minaret of Ibn Tūlūn and el Hakim; in the great circular tower at Amboise, and in the fallen campanile of St Mark's, Venice. (R. P. S.)

STAIRCASE, the term usually applied (Fr. *cage d'escalier*, Ger. *Treppenhaus*) to the stairs leading to the upper floors in a building, including the enclosure walls. In the ordinary house a single staircase only is provided; in larger ones a second or service staircase; in those of more importance, especially where the principal reception rooms are on the first floor, a grand staircase leading to the latter, and other subsidiary stairs or staircases.

Architecture.—Among the earliest examples are those found in Egypt, generally built in the thickness of the walls, as in the pylons and temples; a remarkable example was found by Dr Arthur Evans in Cnossus, in Crete, consisting of a staircase in stone, 6 ft. wide, with return flights of stairs, rising through two floors; the staircase in the temple of Zeus at Olympia leading to the gallery, is supposed to have been in wood, but in some of the Greek temples have been found stairs in stone with return flights. In the Tabularium at Rome there is a long flight of 67 steps leading up from the Forum to a hall at the back, but otherwise there are few examples of ancient Roman staircases, and none of any importance have been found in Pompeii. Of medieval staircases the principal examples are those in stone built round a circular newel, to provide means of ascent to the various stages of the church towers. One of these, at St Gilles in Provence, is covered with a semicircular rising vault, which is known as Vis St Gilles; some of these circular staircases are 12 ft. in diameter, others, like those in the campanile of Pisa, are built in the thickness of a circular hall with well-hole in centre. In the 15th century some of the stone staircases leading to the rood loft, with open tracery round the edge, are of great elaboration and beauty, as at St Maclou, Rouen. In the 16th century in France, in the châteaux of the Loire, are many examples, among which the circular staircases at Blois, two of them in square towers, the third octagonal in plan and on one side open at intervals to the court, has a great circular newel enriched with arabesque carving, and a rising elliptical barrel vault with ribs and bosses. In the château of Chambord the great staircase in the middle, which is built round a circular well-hole, had two separate flights, one over the other, so that, starting from opposite sides on the ground floor, two persons could ascend without seeing one another. At Azay le Rideau, Loire, and in the château of St Germain-en-Laye, the staircases in return flights are built between walls, and the same is found in the ducal palace at Venice and most of the palaces of Rome. At Venice, in the Palazzo Minelli, the staircase is in a circular tower with open arcades and balustrades. The most famous staircase in Spain is that in the north transept of Burgos Cathedral, remarkable for the magnificent iron-work of its balustrade; and in England the staircase leading to the hall of Christ Church, Oxford, with a magnificent fan vault, is a fine example. In the 16th and 17th centuries in England the grand staircases of the great mansions were usually in wood, the finest examples being those at Hatfield, Knole, Audley End, &c. They would seem also to have been regarded as part of the great entrance halls, but in France and Italy they assumed greater importance, being always in stone or marble, with colonnades or arcades round the staircase on the first floor. Of these there were three types. The first is the straight staircase with two or more landings, of which examples existed in Paris in the Tuileries and the old Hôtel de Ville, having been reproduced in the new Hôtel de Ville, and the staircase in the Vatican. The second is the staircase with return flights right and left, at the top of a first flight, sometimes built in long rectangular halls, but unsatisfactory owing to the want of concentration and to the difficulty of deciding whether to turn to the right or left at the top of the first flight; examples are in the Herrenchiemsee Palace, Bavaria, the Palazzo Reale at Naples, the Madama Palace at Turin, and the government offices in London. In the new opera house in Paris, J. L. Garnier (*q.v.*) solved the problem better by placing his staircase in a square hall, which, seen from the first floor surrounded with open balconies, forms one of the finest staircase halls known. The third alternative is that of the staircase in three flights, built round a square well-hole, of which the staircase in Holford House is the best example. The vestibule staircases in Genoa which lead to a raised ground-storey, such as those in the Palazzo Durazzo, or in the university, are extremely fine in effect and are executed all in white marble. As the vestibules are open to the narrow streets, it is possible that the title of the "marble palaces of Genoa" refers to those marble staircase halls, because the external walls of the palaces are either in ordinary stone or in brick covered with stucco. (R. P. S.)

Construction.—The primary object of stairs, in house-building, is to afford a safe and easy communication between floors at different levels. To make the communication easy the "rise" and width (or "tread") of the steps should be regular and suitably proportioned to each other with convenient landings; there should be no winding steps, and the rail which is fixed to render the use of the staircase safe should be strongly fixed with its top at a convenient height for the hand.

The first person that attempted to fix the relation between the height and width of a step upon correct principles was, we believe, Blondel, in his *Cours d'architecture*. His formula is applicable to very large buildings but not to ordinary dwellings. Ashpitel, who investigated the subject at length (in *Handrails and Staircases*), gives the following rules for different proportions of treads and risers:—

Width of tread in inches.	Height of rise in inches.
12	$5\frac{1}{2}$
$11\frac{1}{2}$	$5\frac{3}{4}$
11	6
$10\frac{1}{2}$	$6\frac{1}{4}$
10	$6\frac{1}{2}$
$9\frac{1}{2}$	$6\frac{3}{4}$
9	7

These dimensions give angles of ascent varying from 24° to 37°. The projection of the nosings is not reckoned in the width of the treads and must be added to determine the full width of the treads. It will be seen upon examination that these proportions may be expressed in the following simple formula: 23 = twice the rise in inches + the tread in inches. An American rule is to make the sum of the rise and tread equal to 17 or $17\frac{1}{2}$ in.

The forms of staircases are various, the simplest being a straight flight, which type should only be used to a low storey. In towns, where space cannot be allowed for convenient forms, they are often made angular, circular or elliptical, with winding steps, or are constructed of composite form partly straight and partly circular. In large buildings, where convenience and beauty are the chief objects of attention, winding steps are seldom introduced when it is possible to avoid them. Well-designed stairs should be planned as simply as possible to afford easy and convenient access to the higher level. The staircase must be placed in a position easy of approach, and convenient for both the lower and upper apartments. It must be well ventilated and lighted—the absence of sufficient light may prove the cause of serious accidents. At no part should the head room (that is, the height between the level of a tread and that portion of the structure immediately above it) be less than 7 ft. Straight flights should be composed of not less than four and not more than twelve steps. If it is desired to continue more than this number of steps in a straight line, a landing equal in length at least to the width of the stairs should be provided before starting up the next flight. Winders should be avoided if possible, but should they be found necessary it is advisable to put them at the bottom of a flight rather than at the top, the reason being that should they be the cause of an accident the unfortunate individual will not have far to fall.

Besides the straight flight of stairs, stairs may be designed in almost numberless different ways to suit the position which they are to occupy or with a view to architectural effect, but whatever position or form they are made to take their chief purpose of providing convenient and easy access to a higher level must be steadily borne in mind. Some of the most ordinary forms from which staircases of a more ambitious character are elaborated are the *dog-legged* or *newel* stair, *open newel* stair, *geometrical* stair, *circular newel* stairs (see fig. 1).

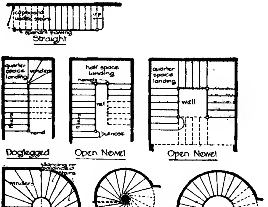

FIG. 1.

The *newel* or *dog-legged* stair is so termed from its supposed resemblance to a dog's hind leg. In this form the staircase is divided in width into two equal parts and the outer string of the upper return of the stairs rises in a vertical plane immediately above that of the lower flight. There is therefore no well-hole in this form of construction (see fig. 4, plan and section).

Open newel stairs, as in the previous example, have newels placed at the angles, but are so arranged as to enclose a well. This is more convenient for the distribution of light than the dog-legged stairs, especially when the lighting is effected by means of a lantern skylight placed at the top of the staircase.

Geometrical stairs usually enclose a well, which may vary very much in size and shape from merely a narrow slit between the flights to a square opening admitting of ample ventilation and lighting. This form has continuous strings and handrail, and may be rectangular, circular or elliptical in plan, although it is especially adapted for the curved forms and most satisfactory when so treated. Such stairs are more difficult to construct than the newel stairs already mentioned and lack their strength, as in the absence of the strong framed newel posts the handrail depends for support entirely upon the balusters, which must therefore be very securely fastened to the treads. When wood balusters for the most part are used bars of iron are often introduced at intervals to afford additional stiffness. *Circular geometrical* stairs are built on a circular plan around a well. Each step is necessarily a *winder* radiating from the *outer string* to the *wall string*. If in wood they must be very carefully framed, especially if the well-hole is small, owing to the difficulty of introducing proper carriages for support, and the number of pieces of which the work must be built up on account of its curvature. This type of stairs is more suitable for building in stone, and in this case support is obtained by pinning the end of the stone step well into the wall and supporting each step upon the one below. The balusters and handrail also, in the case of stone, are much more firmly fixed by the former, which are usually of iron, being let into mortices in the tread or end of the step and run in with molten lead and caulked to secure a firm fixing.

Solid newel or *spiral* stairs are circular or polygonal on plan and built around a central pillar or newel, which may be square, polygonal or circular in section. This also is a form of stair-building especially suitable for erection in stone, the central newel being formed on the step itself, and the other end well pinned into the masonry of the wall. Each succeeding step should be dowelled at the newel to the one below and should lap for a matter of two or three inches at least for its entire length over the one below and in this way obtain extra support.

The newel stair was at its best in Elizabethan and later Renaissance times. The older form of staircase with circular newel and narrow winding steps was found ill adapted to the altered conditions when convenience and elegance were becoming more sought after. The designers of this period found in the open newel stair a construction capable of being developed into a dignified and beautiful feature of domestic architecture, and they certainly brought out its possibilities in a remarkable manner. This is evidenced by the many fine examples, handed down to us by the architects of the Tudor period, to be found in the great mansions which date back to the time of the early Renaissance. Steps were arranged in broad short flights with wide treads and easy rise. Landings were freely used, and in many cases were large enough to be used as galleries for the display of pictures. The work was generally solidly executed in oak, and carved and moulded decoration was lavished upon every detail. The newels, much enriched, were frequently carried up to the ceiling and formed a portion of the arcading which was often a prominent feature around the well. In the period of the later Renaissance the newel principle of construction was still retained and the main features were the same, but they were planned with longer flights and the manner of decoration partook of a more severely classic nature. One of the first examples is that of the Château de Blois, and of modern treatment that of the Grand Opera House, Paris. In the period of the Georgian era the geometrical staircase was much favoured and very generally used in domestic buildings. Although more difficult to build it must be admitted that this type of stair is not so satisfactory in a number of ways as the newel form. With its continuous curving strings and handrail it has a certain elegance of its own, but in principle of construction it is not so good, nor can it compete with the open newel stair in regard to the ease with which the latter lends itself to schemes of artistic decoration. As before remarked, however, it is well adapted for stairs circular and elliptical in plan.

Concrete and Stone Stairs.

Experience has proved concrete to have fire-resisting properties of the most effective character, and it does not possess the propensities for splitting and flying under the action of heat that belong to stone. Steel or iron is often employed as an additional support for stone and concrete stairs. In the case of concrete work iron bars are frequently embedded in the steps for their full length, and are in this way hidden from sight while at the same time serving the purposes of support. When a more ornate appearance is desired than is obtained by the use of plain concrete the steps may be encased in other material to secure a richer effect. Marbles, tiles and mosaic are the principal materials used for this

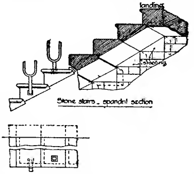

FIG. 2.

purpose. Stairs of fine concrete to which is given the name of "artificial stone" have largely superseded those constructed of genuine stone. It is very strong and capable of being further fortified by the introduction of steel core bars without detriment to its appearance; it is consistent in quality and special shapes are readily moulded; it is very hard-wearing, especially when the aggregate consists of a hard nature such as granite chippings. The stairs are built by pinning each step in the wall either at one or at both ends. In the first case they are termed *cantilever* or *hanging steps*, and it is advisable to use steel reinforcement and pin the end of the step at least 9 in. into the wall. When fixed at both ends the pinning need not be so deep, and unless the stairs are very wide the steel core may be omitted. The steps are either rectangular or spandrel-shaped in section (figs. 2 and 3); the former are stronger and easier to fix than the latter, which, however, give a better appearance and can be finished with a plain smooth soffitt. Iron balusters are generally used for stone and concrete staircases, and are fitted with lug terminations which are let into dovetailed mortices formed in the top or side of the stair tread and held fast by molten lead, neat Portland cement, or a mixture of sulphur and sand.

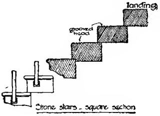

FIG. 3.

The construction of wood staircases forms a special branch of the joinery craft, and many books have been written on the subject.

Staircasing and Handrailing. Numerous methods of setting out the handrails have been put forward by different authors, among them being the tangent system, which gives excellent results at perhaps the smallest cost compatible with good work. It is noteworthy that the common practice in England with regard to wood stairs is to frame and form the finished work in the workshop and fix it bodily in the position it has to occupy. In America, especially in the eastern states, the finished staircase is built up piece by piece upon a rough framework which has been used by the workmen during the erection of the carcase of the building. In many instances the strings consist of easings and panellings nailed upon the rough skeleton work.

Stairs are built in many kinds of materials, such as wood, stone, concrete, iron and brick. Often two or more kinds of materials are used in the same staircase, as when constructions of concrete or stone are reinforced with iron or steel. It is common also to fit to a staircase handrails, balusters and newels of a different nature from the steps themselves. The spandrel or triangular-shaped space between a flight of stairs and the floor is frequently enclosed with wood-panelled framing and fitted with a door so that it may be made use of for cupboard accommodation.

There are a number of technical terms connected with staircases which require some explanation to enable the drawings to be easily understood:—

Staircase.—This comprises the whole of the stair construction and is the name given to the space or enclosure which contains the stairs.

Well-hole, the open space enclosed by the stairs.

Flight, a continuous series of steps between two landings.

Landing, a platform forming a kind of halting-place between two flights of stairs. A *quarter-space landing* forms a space, usually a rectangle, equal in width and length to the breadth of the two flights which it separates. A *half-space landing* extends the total width of the staircase.

Flier.—Fliers are steps that have the nosings of the treads parallel one to another.

Winder.—This is an angular-shaped step. A winder fitted into a wall angle is often termed a *kite winder*, from the fact that it resembles a kite. In planning stairs the width of the winder tread at a distance of 18 or 20 in. from the handrail should equal the width of a flier.

Curtail Step.—This may be either a flier or a winder. One or both ends of the step are projected to form a base for the newel and are shaped to a scroll which often follows the line of the curve terminating the handrail. It is usually the step or steps at the base of a staircase that are formed in this way.

Bull-nosed step, one having a blunt rounded end. It may be shaped to a quarter or half circle.

Dancing Stairs.—The introduction of winders in geometrical staircases brings about awkward complications in the curve of the handrail and strings, for the width of the winding steps at the handrail being much less than that of the fliers, while at the same time the rise is necessarily equal, causes an unsightly knee in the handrail and in the strings. To obviate this the whole of the steps are made to dance, that is, they are all shaped as winders in order to divide the going equally between them and thus obtain a regular slope for the strings and handrail. Often the first and last three or four steps of a flight are made ordinary fliers. In a polygonal or elliptical staircase the whole of the flight is constructed in this way so as to obtain a regular sweep up from the bottom to the top *step*. Each step may be divided into several different parts such as the *tread*, the *riser* and the *nosing*. The tread is the horizontal upper surface of the step which supports the foot when ascending or descending the stairs. The riser is the upright member of a step which supports the tread. It fills in the vertical space between the nosing of one tread and the back edge of the one below. The edge of the tread usually projects some little distance beyond the face of the riser and is formed into a rounded or moulded nosing. Stone stairs and those of concrete usually have each step formed separately in a solid piece of stone of square or triangular section, and these are fixed in position by being pinned into the wall at one or both ends with each step resting upon the back edge of the one below. Stairs of costly marble are frequently built up in a manner somewhat similar to that adopted for wood construction.

Rise, the vertical distance between the surface of one tread and that of the next.

Going, the horizontal measurement between two adjacent risers. In America this is termed the *run*.

Newels, strong posts occurring at intervals in a newel staircase. They are placed at the ends of flights where junction is made to landings, at turnings, and at the top and bottom of the staircase. They should be strongly framed in the stair construction, and have the string and handrail housed into them. Newels are sometimes of iron, and in large stone staircases of stone. They are sometimes of elaborate form and often designed as a pedestal carrying a lamp or statuette, or they may be carried up to form part of some ornamental framing around the staircase. In America the *newel* is the main post where the stairs begin, and the remainder of the posts used in the framing are termed *angle posts*.

Handrail.—This is a rail commonly of hard wood which runs up at the same slope as the stairs at a height above the nosing line of about 2 ft. 8 in. (that is 3 ft. minus half a rise) to the upper surface of the rail. On the level, such as on landings, it is usually fixed 3 ft. above the surface. These are the heights at which a handrail is found to give most assistance to persons going up or down stairs. Handrails are made in other materials such as iron and bronze. A handrail is generally upheld by *balusters*, which are vertical bars or posts filling in the space between the handrail and the string or the treads. They are made in many shapes and in many different materials such as wood, iron, bronze, stone and marble. Sometimes in the place of balusters the space usually occupied by them is filled in with scrollwork of wrought or cast iron or bronze, or with panels of wood perforated, perhaps, and richly carved.

Core-rail.—An iron band is frequently used in geometrical stairs to give extra strength and stiffness to the handrail. It is generally about ¼ in. thick, being screwed into a groove formed in the underside of the handrail. It is especially necessary for the curved portions of the handrail, where the grain of the wood is often cut across.

String.—Strings are the members that carry the treads and risers which in wood stairs are housed into them or else fitted into notches cut in the strings to receive them. In the former case the supporting member is termed a *close string*, but if notched out for the steps it is known as a *cut string* (see details, fig. 4). A *cut and mitred string* is similar to this last, but has the vertical cut of each notch splayed and the riser is mitred to it so as not to show the joint. Strings are either *wall strings* or *outer strings*; the former are fixed against the wall, the latter run up from newel to newel or in geometrical stairs ramp and curve according to the nosing line. *Rough strings* or *rough carriages* are placed between the inner and outer strings to afford additional support to the treads and risers, and *rough brackets* about 1 in. thick are fitted into the steps and spiked to the carriages.

Ramp.—This is a concave curve formed in one plane when changing the direction of the handrail or string. In America it is known as an *easing*.

Knee.—This is a convex curve in one direction. When used in conjunction with a ramp it forms a *swan-neck*, which is a combination of ramp and knee.

Wreath.—This is a curve formed both horizontally and vertically in the handrail or string. It is often necessary in geometrical stairs where a change of direction takes place.

Moving Inclines. Although more in the nature of a mechanical lift or elevator than a stair, moving stairways may perhaps find a place in this article owing to their resemblance and to the fact that their object is to convey the passenger quickly and easily to a higher level without the necessity of a tedious climb up stairs, or of a wait such as is often entailed with a vertical lift. The contrivance consists of an endless inclined platform formed of links bolted together, which allow it to travel round wheels fixed at the top and bottom of the stairway and hidden within its framing. This is kept in continual motion by mechanical means, usually by an electric motor, which causes it to travel at the rate of about 100 ft. a minute. The handrail also moves at the same rate, so that a passenger merely steps on to the lower portion of the stair, places his hand upon the handrail, and is carried swiftly and safely up to the next floor, where he is deposited without any effort on his part. The process of stepping on and getting off the stairway is amazingly simple and without any element of danger to the passenger. For high buildings, underground railways and similar positions, a spiral form is used which winds round in a circular shaft to the highest level and returns in the opposite direction in a similar manner, taking up and setting down passengers as it revolves. Although this type of elevator is probably not so rapid as the vertical lift working in a straight line to the point it is desired to reach, its great advantage is that it does away with the waiting which often causes so much annoyance with ordinary lifts.

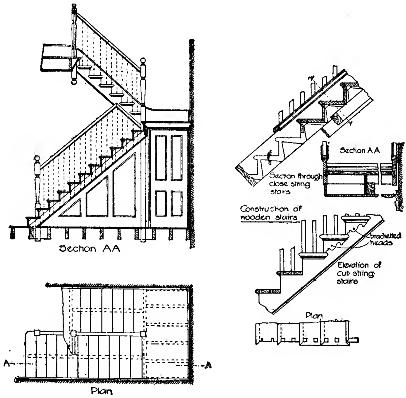

FIG. 4.

The by-laws of the London County Council contain many stipulations regulating the construction of staircases, and these are summarized below. In every public or other building of more than 125,000 cub. ft. constructed to be used as a dwelling for separate families the floors of lobbies, corridors, passages, landings, and also the flights of stairs, shall be of fire-resisting materials. The principal staircase of every dwelling-house shall be ventilated by means of a window or skylight opening directly into the external air. In buildings occupied in separate tenements by more than two families the common staircase shall be ventilated upon each storey above the ground storey by windows or skylights, or otherwise adequately ventilated. Staircases in churches, chapels, public halls, lecture rooms, exhibition rooms and buildings for similar purposes are subject to the following conditions: Stairs shall be supported and enclosed by brick walls at least 9 in. thick. The treads of each flight shall be of uniform width, and stairs, corridors or passages shall be 4 ft. 6 in. wide unless the building is for the accommodation of less than two hundred persons, when it may be 3 ft. 6 in. wide. If for more than four hundred persons the width must increase by 6 in. for each additional hundred persons up to a maximum of 9 ft. Staircases 6 ft. wide and upwards shall be divided by a handrail. Two staircases may be substituted for one large one, each to be two-thirds the width required for the single stair, but not less than 3 ft. 6 in. Accommodation upon different levels must be provided with separate stairs leading directly to the street or open. Exit doors must open outwards. Under the theatre regulations dated 1892 the same widths hold good, but the minimum width is increased to 4 ft. 6 in. Every staircase for the use of the audience shall have solid square section steps of approved stone or concrete with treads of uniform width not less than 11 in. wide or rise greater than 6 in. Winders are prohibited, and the flights must have not more than twelve steps nor less than three steps each. Both ends of each step shall be pinned into the wall. The several flights shall be supported and enclosed on all sides by brick walls not less than 9 in. thick carried down to the level of the footings. Not more than two flights of twelve steps each shall be constructed without a turn. Landings to be 6 in. thick, square on plan and supported under the middle by 9 in. brick arches. A continuous handrail supported on strong metal brackets to be fixed on both sides of steps and landings, and if possible chased into the wall to avoid projection. The roof over the staircase shall be of fire-resisting materials. Separate exits are required for different parts of the theatre or hall.

Law.

The Factory and Workshop Act 1901 contains somewhat similar conditions, but in this case the staircases communicate with each floor and the roof. The minimum width of tread shall be 10 in. and the maximum rise 7½ in. Steps of spandrel section may be used having a thickness of 3 in. at the smallest part for staircases 3 ft. 6 in. wide, and not less than 4½ in. thick for staircases 4 ft. 6 in. wide. External fire escape stairs must be constructed with dead bearings and without cantilever work. They must comply with the requirements for enclosed staircases as regards width, going, width of treads, height of risers, doors, handrails, &c. They must deliver at the ground-level into a public way or some large space. Where in general use the treads must be of non-slippery material as distinguished from perforated iron or chequered iron plates.

The second schedule of the London Building Act 1894 sets forth the materials that are deemed fire-resisting under the act, and specific in the case of staircases "oak or teak or other hard timber with treads and risers not less than 2 in. thick."

The law regulating the construction of buildings in the city of New York provides that "stairways serving for the exit of fifty people must, if straight, be at least 4 ft. wide between railings or between walls, and if curved or winding 5 ft. wide, and for every additional fifty people to be accommodated 6 in. must be added to their width. In no case shall the risers of any stairs exceed 7½ in. in height, nor shall the treads exclusive of nosings be less than 10½ in. wide in straight stairs. In circular or winding stairs the width of the tread at the narrowest end shall not be less than 7 in."

STALACTITES (Gr. σταλακτός, from σταλάσσειν, to drip), pendent masses formed where water containing mineral solutions drops very slowly from an elevation. They are seen, for example, beneath bridges, arches and old buildings as water percolating through the joints of the masonry has dissolved very small quantities of the lime present in the cement and mortar between the stones. On exposure to the air part of the water evaporates and the solution of carbonate of lime becomes supersaturated; a deposit of this substance ensues and as the drop continues to fall from the same spot a small column of white calcite very slowly grows downwards in a vertical direction from the roof of the arch. In a very similar manner stalactites of ice are produced in frosty weather as the water dropping from eaves of buildings, beams, branches of trees, &c., very gradually freezes. Other minerals than ice and calcite often occur in stalactitic growths. Thus we find in mines and in the cavities of mineral veins stalactites of limonite, fluorspar, opal, chalcedony and gibbsite. These stalactites are never of great size, usually not more than 2 or 3 in. in length, and probably the method of origin is exactly the same as that of the larger and more common stalactites of ice and of calcite.

The conditions essential to the perfect development of stalactites appear to be (1) a very slow trickle of water from a fissure; (2) regular evaporation; (3) absence of disturbance, such as currents of air. If the discharge of water is fast, irregular encrustations may be produced, or the precipitate of solid matter may be entirely washed away by the mechanical force of the currents. Changes of temperature will interfere with evaporation, sometimes accelerating and sometimes retarding it, and the stalactites tend under such circumstances to stop growth or to develop irregularities and excrescences. Currents of wind produce the same effect. For these reasons ice stalactites form most readily on calm cold nights, and stalactites of ice or calcite are seen in greatest perfection in the interior of caves, where the sun's light does not penetrate, the temperature is steady, and there are no strong currents of air.

In all limestone caves stalactites form in great abundance as glimmering white columns covered with a thin film of water. The great caves, such as those of Adelsberg (in Styria), Jenolan (Australia), the Mammoth Cave (Kentucky), the Causses district in France, and the grottos of Belgium, are divided into chambers which are richly festooned with stalactites, and fanciful names are given to various groups according to their similarity to different objects, natural or artificial. Ice caves of considerable size occur in the Arctic and Antarctic regions, and are draped with ice stalactites often wonderfully like those of limestone caves.

Where the water drops upon the floor of one of these caves evaporation still goes on and an encrustation forms which may cover the whole surface as an irregular sheet. If the air be perfectly still, however, the drop which falls from a stalactite on the roof will always land on the same place and a pillar of deposit will rise vertically, till in course of time it meets and joins with the stalactite above. In this way a column is produced, which sometimes has a graceful form with a long straight shaft expanding somewhat at its upper and lower extremities. As the stalactites thicken by deposit of layer upon layer of carbonate of lime, they rarely continue to be cylindrical but assume tapering forms with irregular surfaces. They seldom branch, but sometimes they give off excrescences which may curve upwards or downwards and occasionally long thin stalactites take their rise from these and grow downwards parallel to the main stalactite. Large stalactites may be three or four feet thick, but in that case they have usually formed by the coalescence of adjacent ones which enlarged till they met and were then covered with a continuous layer of deposit. Single stalactites 2 ft. in diameter are not rare. It is known that they are of very slow growth, and much speculation has gone on regarding the length of time required for the formation of some of the largest stalactites. From data obtained by measurement of the rate of growth at the present day it has been estimated that as much as two hundred thousand years may have elapsed since certain thick stalactites began to grow. We know that many caves are of great antiquity from the fossil remains they contain, but these estimates are probably ill-founded, seeing that there is no certainty that the conditions have remained the same during the whole period of growth. Sir Archibald Geikie records that stalactites 1½ in. in diameter had formed beneath a bridge in Edinburgh which was a hundred years old; in caves, however, the rate of formation is rarely so great as this. Inscriptions on stalactites in the Adelsberg cave after thirty years had been covered with a scarcely perceptible film of new deposit. In one of the Moravian caves a stalactite, about as thick as a goose quill, was broken across in 1880 and in 1891 it had grown three or four centimetres; from careful observations it has been calculated that one of these stalactites, 7 ft. long, may have been formed in 4000 years. The stalagmitic crust on the floor of caves is usually mixed with blocks which have fallen from the roof, sand, mud and gravel carried in by floods, and the bones of animals and men which have inhabited the cave if it had an accessible entrance. Its formation must have been interrupted by many changes in the physical conditions of the district, and consequently it often occurs in layers which alternate with beds of a different character.

Some particulars regarding the internal structure and growth of stalactites have been ascertained by Professor W. Rinz of Brussels. The first stage of every stalactite is a low circular ring of deposit on the roof of the cave. The diameter of this ring corresponds to the breadth of a drop of water which is so large that it is on the point of falling. At the outer surface of the drop evaporation goes on and supersaturation results in the deposit of a thin ring-shaped band. At the centre of the drop no deposition takes place, and as this goes on after some time a short tube is produced; the width of this tube is about 5 millimetres and is fairly constant. The tube very slowly lengthens as deposit gathers at its lower end: water is constantly dropping from it and its interior is always full. Very little material is deposited except at the orifice—hence in many caves long straight tubular stalactites can be seen not much more than a quarter of an inch wide, and with delicate thin walls. A little water, however, makes its way from the interior to the outside of the tube and is exposed to evaporation there, consequently the tube walls gradually grow thicker. The end of a simple tubular stalactite of this type has small sharp teeth or points which are the corners of crystals. These have the rhombohedral faces of calcite, and are usually of a simple description: their corresponding faces are parallel, and an examination of the material of the tube proves that the whole mass has the same crystalline structure. We may, in fact, describe these stalactites as rounded, tubular crystals continuously growing but provided with crystalline facets only at their lower ends. Small lateral passages sometimes allow the water to escape from the interior of the tube and their apertures become surrounded with lime deposits. In this way horns, twigs and branches arise, often curving upwards or downwards; they are always provided with a central tubule which may be a mere capillary. The substance of these offshoots is in crystalline continuity with that of the main stalactite, and the whole mass has a uniform optical orientation. In the majority of cases the long axis of the stalactite corresponds to the optic axis of the calcite crystal, but in one group of stalactites these two make an angle of 15° with one another. An interruption in the supply of water or an accidental fracture of the stalactite induce abnormal growth. The end of the tube becomes obstructed or completely closed, and nodular or tuberculate growths are often the result. If the outer surface dries the next layer which is laid down may often be readily detached, as it is not firmly united with the underlying material. In any case a second stage of growth ultimately arrives, when the central tube is no longer the chief conduit but a general drip of water from the roof bathes the whole outer surface of the stalactite. Then small, flat crystals of calcite appear with their basal planes directed outwards. These increase in number till they cover the whole mass, and as they grow outwards they develop into prisms whose axes are directed radially. In very old spherulites the initial tube is covered with a great thickness of radiating calcite crystals deposited from the mineral solutions which trickle down along the external surface. When they are cut across they show concentric rings, some of which are due to stains of iron or manganese oxides or insoluble materials brought down by the water; others are lines of cavities produced by interrupted or irregular crystallization. They resemble the rings of the wood of trees, but probably do not depend on seasonal changes but on purely accidental factors, so that they afford no clue to the rate of growth.

Stalactites also occur in the interior of lava caves in the Sandwich Isles, Samoa, &c. Often the upper surface of a lava flow has cooled to form a crust, while the interior is still perfectly fluid, and it sometimes happens that the liquid basalt has made its escape, leaving great cavities below the hollow roof of the lava. The interior of these caves is covered with a black shining film of glassy basalt, and black stalactites of lava hang downwards. Their surface is sometimes changed to brown or red by the oxidizing action of the acid vapours which occupied the cave after the lava retired. These stalactites are tubular, with bluntly rounded ends, and probably their mode of growth is somewhat analogous to that of ice-stalactites. In microscopic section they prove to be glassy with small crystals of olivine and augite; in this they differ from the ice and calcite stalactites which are crystalline throughout.

STALL (O. Eng. *steall*, *stael*, cf. Du. *stal*, Ger. and Swed. *Stall*, a common Teutonic word for a place, station, place for standing in; the root is the Indo-European *sta-*, to stand, seen also in Latin *stabulum*, Greek *σταθμός*, and in stallion, an entire horse, properly one kept in a stall and not worked), a word which means literally a place where one may stand, and so is applied to a separate division in a stable, shed, &c., in which a single horse, cow or other domestic animal may be kept, to a separate booth, bench or table in a market or other building, or in the street, on which goods are exposed for sale by the person owning or licensed to use the same, and in England to the higher-priced seats on the ground floor of a theatre. The word is more particularly applied to a special form of seat in an ecclesiastical building. In cathedrals, monastic churches and the larger parish churches the stalls are fixed seats enclosed at the back and separated at the sides by high projecting arms, and placed in one or more rows on the north and south sides of the choir or chancel, running from the sanctuary to the screen or chancel arch. These separate enclosed seats are properly reserved for the clergy, and more usually the choir are seated in open benches in front of the stalls. In a cathedral the canons and prebendaries have each a stall assigned to them.

In the chapels of the various knightly orders the stalls are assigned to the members of the order, thus, in St. George's Chapel, Windsor, are the stalls of the Knights of the Garter, in Henry VII.'s Chapel in Westminster Abbey are those of the Knights of the Bath, adorned with the stall plates emblazoned with the arms of the knight occupying the stall, above which is suspended his banner.

Architecturally and artistically considered, the stalls of a cathedral or church are a marked feature of the interior adornment. They are richly carved, and are frequently surmounted by canopies of tabernacle work. The seats generally can be folded back so as to allow the occupant to stand upright or kneel; beneath the seat, especially in monastic churches, is fixed a small bracket, a *miserere* (*q.v.*), which affords a slight rest for the person while standing. Among beautiful specimens of carved stalls may be mentioned the Early Decorated stalls in Winchester Cathedral, the Early Perpendicular ones in Lincoln Minster, and the early 15th-century canopies in Norwich Cathedral. The stalls, especially the towering corner-stalls with their ornate carving filled with figures, in Amiens Cathedral are very fine; they date from 1508–1520.

STALLBAUM, JOHANN GOTTFRIED (1793–1861), German classical scholar, was born at Zaasch, near Delitzsch in Saxony, on the 25th of September 1793. From 1820 until his death on the 24th of January 1861 Stallbaum was connected with the Thomasschule at Leipzig, from 1835 as rector. In 1840 he was also appointed extraordinary professor in the university. His reputation rests upon his work on Plato, of which he published two complete editions: the one (1821–1825) a revised text with critical apparatus, the other (1827–1860) containing exhaustive prolegomena and commentary written in excellent Latin, a fundamental contribution to Platonic exegesis. A separate edition of the *Parmenides* (1839), with the commentary of Proclus, deserves mention. Stallbaum also edited the commentaries of Eustathius on the *Iliad* and *Odyssey*, and the *Grammaticae latinae institutiones* of Thomas Ruddiman.

See C. H. Lipsius in the *Osterprogramm of the Thomasschule* (1861); R. Hoche in *Allgemeine deutsche Biographie*, vol. xxxv.

STALYBRIDGE, a municipal and parliamentary borough of Cheshire, England; the parliamentary borough extending into Lancashire. Pop. (1901), 27,673. It lies on the river Tame, in a hilly district, 6 m. E. of Manchester, and is served by the London & North-Western, Great Central, and Lancashire & Yorkshire railways. Immediately to the west lie the towns of Dukinfield, and across the river in Lancashire, Ashton-under-Lyne; while 2 m. south of Stalybridge is the town of Hyde. The whole district is thus very densely populated. Stalybridge is one of the oldest seats of the cotton manufacture in this locality, the first cotton mill having been erected in 1776, and the first steam engine in 1795. There are also machine works, nail works, paper mills, and iron and brass foundries. The development of the town is modern, as it was created a market town in 1828, incorporated in 1857, and created a parliamentary borough, returning one member, in 1867. It is under a mayor, 7 aldermen and 22 councillors. Area, 3130 acres.

STAMBOLOV, STEFAN (1854–1895), Bulgarian statesman, was born on the 31st of January 1854 at Trnovo, the ancient Bulgarian capital, where his father kept a small inn. Under Turkish rule it was impossible to obtain a liberal education in Bulgaria, and young Stambolov, after attending the communal school in his native town, was apprenticed to a tailor. During the politico-religious agitation which preceded the establishment of the Bulgarian exarchate in 1870, a number of Bulgarian youths were sent to Russia to be educated at the expense of the Imperial government; among them was Stambolov, who was entered at the seminary of Odessa in order to prepare for the priesthood. His wayward and independent nature, however, rebelled against the discipline of school life; he was expelled from the seminary on the ground of his association with Nihilists, and, making his way to Rumania, he entered into close relations with the Bulgarian revolutionary committees at Bucharest, Giurgevo and Galatz. In 1875, though only twenty years of age, he led an insurrectionary movement at Nova Zagora in Bulgaria, and in the following year organized another rising at Orekhovitza. In the autumn of 1876 he took part as a volunteer in the Servian campaign against Turkey, and subsequently joined the Bulgarian irregular contingent with the Russian army in the war of 1877–78. After the signature of the Berlin Treaty in 1878 Stambolov settled at Trnovo, where he set up as a lawyer, and was soon elected deputy for his native town in the Sobranye. His force of character, his undoubted patriotism, his brilliant eloquence, and his disinclination to accept office—a rare characteristic in a Bulgarian politician—combined to render him one of the most influential men in Bulgaria. The overthrow of the Zankoff ministry in 1884 was largely due to his influence, and in that year he was nominated to the presidency of the Sobranye. He held this important office for the next two years, a critical period in the national history. The revolution of Philippopolis, which brought about the union of Bulgaria with eastern Rumelia, took place on the 18th of September 1885, and it was largely owing to Stambolov's advice that Prince Alexander decided to identify himself with the movement. The war with Servia followed, and Stambolov, notwithstanding his official position, served as an ordinary soldier in the Bulgarian army. After the abduction of Prince Alexander by a band of military conspirators (Aug. 21, 1886) Stambolov, who was then at Trnovo, acted with characteristic promptitude and courage. In his capacity as president of the Sobranye he established a loyal government at Trnovo, issued a manifesto to the nation, nominated his brother-in-law, General Mutkurov, commander-in-chief of the army, and invited the prince to return to Bulgaria. The consequence of these measures was the downfall of the provisional government set up by the Russophil party at Sofia. On the abdication of Prince Alexander (Sept. 8) Stambolov became head of a council of regency, with Mutkurov and Karavelov as his colleagues; the latter, however, soon made way for Jivkov, a friend and fellow townsman of the first regent. Invested with supreme power at this perilous juncture, Stambolov displayed all the qualities of an able diplomatist and an energetic ruler. He succeeded in frustrating the mission of General Kaulbars, whom the Tsar despatched as special commissioner to Bulgaria; in suppressing a rising organized by Nabokov, a Russian officer, at Burgas; in quelling military revolts at Silistra and Rustchuk; in holding elections for the Grand Sobranye, despite the interdict of Russia, and in securing eventually the election of Prince Ferdinand of Coburg to the vacant throne (July 7, 1887). Under the newly-elected ruler he became prime minister and minister of the interior, and continued in office for nearly seven years (see BULGARIA). The aim of his foreign policy was to obtain the recognition of Prince Ferdinand, and to win the support of the Triple Alliance and Great Britain against Russian interference in Bulgaria. In his dealings with Turkey, the suzerain power, he displayed considerable acuteness; he gained the confidence of the Sultan, whom he flattered and occasionally menaced; and aided by the ambassadors of the friendly powers, he succeeded in obtaining on two occasions important concessions for the Bulgarian episcopate in Macedonia (see MACEDONIA), while securing the tacit sanction of the Porte for the technically illegal situation in the principality. With the assistance of Austria-Hungary and Great Britain he negotiated large foreign loans which enabled him to develop the military strength of Bulgaria. Under Prince Ferdinand he pursued the same despotic methods of government which had characterized his administration during the regency; Major Panitza, who had organized a revolutionary conspiracy, was tried by court-martial and shot at Sofia in 1890; four of his political opponents were hanged at Sofia in the following year, and Karavelov was sentenced to five years' imprisonment. His tyrannical disposition was increased by the assassination of his colleague, Beltchev, in 1891, and of Dr Vlkovitch, the Bulgarian representative at Constantinople, in 1892, and eventually proved intolerable to Prince Ferdinand, who compelled him to resign in May 1894. He was now exposed to the vengeance of his enemies, and subjected to various indignities and persecutions; he was refused

permission to leave the country, and his property was confiscated. On the 15th of July 1895 he was attacked and barbarously mutilated by a band of Macedonian assassins in the streets of Sofia, and succumbed to his injuries three days later. His funeral, which was attended by the representatives of the powers at Sofia, was interrupted by disgraceful riots, and an effort was made to perpetrate an outrage on his remains. No attempt was made to arrest his murderers; two persons were, however, arraigned for the crime in 1896, and subjected to almost nominal penalties.
(J. D. B.)

STAMFORD, HENRY GREY, 1st Earl of (*c.* 1599–1673), eldest son of Sir John Grey, succeeded his grandfather, Henry Grey as Baron Grey of Groby in July 1614. He married Anne, daughter of William Cecil, 2nd earl of Exeter, the heiress of the borough and manor of Stamford, and in March 1628 was created earl of Stamford. Just before the outbreak of the Civil War he ranged himself definitely among the king's opponents, and was made lord-lieutenant of Leicestershire. After some operations around Leicester he occupied Hereford, and, when compelled to abandon the city, marched into Cornwall. At Stratton, in May 1643, his troops were beaten by the Royalists; driven into Exeter, Stamford was forced to surrender this city after a siege of three months. The earl, who was certainly no general, was charged with cowardice, and took no further part in the military operations of the war, although once or twice he was employed on other business. The ravages of the Royalists had reduced him to poverty, and, distrusted by the House of Commons, he had great difficulty in getting any compensation from parliament. After a period of retirement Stamford declared for Charles II. during a rising in August 1659, and was arrested, but was soon released. He died on the 21st of August 1673. One of his sons was Anchitell Grey (d. 1702), the compiler of the *Debates of the House of Commons, 1667–1694* (10 vols. 1769). His eldest son, Thomas, Lord Grey of Groby (*c.* 1623–1657), was member of parliament for Leicester during the Long Parliament, and an active member of the parliamentary party. In January 1643 he was appointed commander-in-chief of the forces of the parliament in the midland counties and governor of Leicester. In 1648 he won some credit for his share in the pursuit and capture of the duke of Hamilton; he assisted Colonel Pride to "purge" the House of Commons later in the same year; and he was a member of the court which tried the king, whose death-warrant he signed. A member of the council of state under the Commonwealth, Grey fought against the Scots in 1651, and in February 1655 he was arrested on suspicion of conspiring against Cromwell. He was, however, soon released, but he predeceased his father in April or May 1657.

Thomas (*c.* 1654–1720), only son of the last named, succeeded his grandfather as 2nd earl of Stamford. He took some part in resisting the arbitrary actions of Charles II., and was arrested in July 1685; then after his release he took up arms on behalf of William of Orange, after whose accession to the throne he was made a privy councillor and lord-lieutenant of Devonshire. In 1697 he became chancellor of the duchy of Lancaster, and in 1699 president of the board of trade, being dismissed from his office on the accession of Anne in 1702. From 1707 to 1711, however, he was again president of the board of trade. On his death without children on the 31st of January 1720 his titles passed to his cousin Henry (d. 1739), a grandson of the first earl, from whom the later earls were descended.

STAMFORD, a city of Fairfield county, Connecticut, U.S.A., in a township of the same name, in the south-western part of the state, on Long Island Sound, 33½ m. (by rail) N.E. of New York City. Pop. of the city (1900), 15,997, of whom 4078 were foreign-born; (1910, census) 25,138; of the township, including the city (1900), 18,839; (1910), 28,836. The city is served by the New York, New Haven & Hartford railway (which has other stations in the township at Glenbrook, Springdale and Talmadge Hill), by electric railway to Darien, Greenwich, &c., and by two lines of steamboats to New York City and ports on the Sound. The city is pleasantly situated with the Rippowam river flowing through it, the Mianus river on the west and the Noroton on the east. It is the place of residence of many New York business men. Among its institutions are the Ferguson Library (1882; with 16,000 volumes in 1909), several private schools, a Y.M.C.A., the Stamford Hospital (private, 1893), two private sanatoria, the Convent of our Lady of Lourdes, St John's Church House, a day nursery (1902), with dispensary and kindergarten, and the Stamford Children's Home (1895). The Stamford and the Corinthian Yacht Clubs have club-houses here. Shippan Point, on the Sound, 1½ m. south of the city, is a summer resort, near which the city bought land for a public park in 1906. Stamford's factory product in 1905 was valued at $5,890,416, 50·3% more than in 1900. The principal manufactures are builders' hardware, locks and keys (the works of the Yale & Towne Manufacturing Company are here), woollen goods, dye stuffs, &c. The township of Stamford, known until 1642 by the Indian name of Rippowam, was settled in 1641 by twenty-nine persons who for religious reasons seceded from the Wethersfield church and joined the colony of New Haven. Discontent with the religious policy of New Haven, however, caused a number of the Stamford citizens to withdraw and to found Hempstead, Long Island, and for the same reason many of the people of Stamford approved of the union of the New Haven colony and Connecticut by the charter of 1662; and in October 1662 Stamford submitted to Connecticut. Stamford was chartered as a borough in 1830 and as a city in 1894.

See E. B. Huntington, *History of Stamford* (Stamford, 1868); and C. B. Gillespie. *Picturesque Stamford* (Stamford, 1893).

STAMFORD, a market town and municipal borough, chiefly in the South Kesteven or Stamford parliamentary division of Lincolnshire, but partly in Northamptonshire, on the river Welland, at the landward edge of the fen country. Pop. (1901), 8229. The town stands picturesquely on the steep banks of the river, and is of the highest antiquarian interest. It formerly possessed fourteen parish churches, but now has only six, viz. St Mary's, erected at the end of the 13th century, possessing an Early English tower, with Decorated spire, the principal other parts of the building being Perpendicular; All Saints', also of the 13th century, the steeple being built at the expense of John Browne, merchant of the staple at Calais, in the beginning of the 15th century; St Michael's, rebuilt in 1836 on the site of the one erected in 1269; St George's, Early English, Decorated, and Perpendicular, for the most part rebuilt in 1450 at the expense of William Bruges, first garter king-at-arms; St John Baptist's, Perpendicular, erected about 1452; and St Martin's, Perpendicular, in which Lord Treasurer Burghley is buried. Formerly there were several religious houses: the Benedictine monastery of St Leonard's, founded in the 7th century, of which there are some Norman and later remains; the Carmelite monastery (1291), of which the west gate still stands; and houses for Grey Friars (time of Henry III.), Dominicans (1240), Gilbertines (1291), and Augustinians (1316). The principal secular buildings are the town hall (rebuilt 1776), the corn exchange (1859), and the literary and scientific institute (1842), with a library of 6000 volumes. There are a large number of charitable institutions, including the Stamford and Rutland infirmary (1828), Browne's hospital, founded in the time of Richard III., with its picturesque Late Perpendicular building, Snowden's almshouses (1604), Truesdale's almshouses (1700), and Burghley hospital, founded by Lord Treasurer Burghley (1597). The modern grammar school building incorporates remains of the church of St Paul. To the south of Stamford, in Northamptonshire, is Burghley House, the seat of the marquis of Exeter, a fine quadrangular mansion dating from 1587, containing a noteworthy art collection. It stands in a well-wooded park. The prosperity of the town depends chiefly on its connexion with agriculture. It possesses iron foundries, agricultural implement works, wagon factories and breweries. There is also some trade in coal, timber, stone and slates. The town is governed by a mayor, 6 aldermen and 18 councillors. Area, 1918 acres.

Apart from the tradition preserved by Henry of Huntingdon that the Saxons here defeated the Picts and Scots in 449, Stamford (*Staunford*) is a place of great antiquity. The Danes built a fort here on the north bank of the Welland, round which a town existed when in 922 King Edward fortified the opposite side of the stream. It passed again into Danish hands and was one of the five boroughs recaptured by Edmund Ætheling in 941. The priory of St Leonard was a cell of Durham, and a charter of Edgar dated 972 mentions a market and a mint. In the reign of Edward the Confessor Stamford was a royal borough governed by twelve lawmen, reduced in 1086 to nine, and divided into six wards. The Norman castle, built before 1086, was thrice besieged by Henry II. while Duke of Normandy, but only yielded in 1153. Two years later he granted it and the manor to Richard Humet; forfeited by his son it was given to John, earl of Warenne, in 1206. In 1337 it passed to William de Bohun, earl of Northampton, and thence to Edmund Langley, afterwards duke of York, finally reverting to the Crown on the death of Cicely, duchess of York. Elizabeth granted it to the first Lord Burghley. The barons met here in 1215 on their march to London, and in 1309 a parliament was held at Stamford. In 1256 Henry III. gave the burgesses freedom from tolls, the right of receiving tolls and immunity of their goods from arrest, privileges confirmed and enlarged in the following year. William, earl of Warenne, in 1275 permitted the burgesses to choose their chief officer or alderman, who was still sworn in at the manor court as late as 1615 and was first called "mayor" in 1663. Edward IV. incorporated Stamford by the name of the alderman and burgesses in 1461 and granted the town immunity from all external jurisdiction and gave it a common seal. The charters have been frequently confirmed. As early as 1292 Stamford was well known for its monastic schools, and in 1333 was chosen as the headquarters of the students who seceded from Oxford, and an Early Decorated gateway remains of Brasenose Hall. The attempt to establish a regular university was prohibited by royal authority. The defeat of the Yorkists here was followed by the decay of the castle in the reign of Richard III., and the history of the place henceforth centred chiefly round the family of Cecil, whose ancestor, David Seyceld, settled here about 1566. Stamford occasionally returned two members to parliament from 1295 until 1832. The representation was reduced to one by the act of 1867, and was abolished in 1885. The fairs are of ancient origin, and are mentioned in 1245 and the reign of Edward I. These are the May fair, town fair, and spring fair, and fairs on various dates representing Candlemas, mid-Lent, the feasts of Corpus Christi, St James and SS. Simon and Jude. A market is still held every Friday. In 1182 there were dyers, weavers and fullers here, but these were only the usual home industries. In 1822 silk throwsting was successfully carried on, but this has long ceased.

See E. C. Mackenzie-Walcott, *Memorials of Stamford, past and present* (Stamford, 1867); John Drakard, *The History of Stamford in the County of Lincoln, comprising its ancient progressive and modern state* (Stamford, 1822); Charles Nevinson, *History of Stamford* (Stamford, 1879); *Victoria County History: Lincoln.*

STAMMERING, or STUTTERING, a spasmodic affection of the organs of speech in which the articulation of words is suddenly checked and a pause ensues, often followed by a repetition in rapid sequence of the particular sound at which the stoppage occurred. Of this distressing affection there are many grades, from a slight inability to pronounce with ease certain letters or syllables, or a tendency to hesitate and to interject unmeaning sounds in a spoken sentence, to the more severe condition in which there is a paroxysm of spasms of the muscles, not only of the tongue and throat and face, but even of those of respiration and of the body generally. To understand in some degree the explanation of stammering it is necessary to consider shortly the physiological mechanism of articulate speech. Speech is the result of various muscular movements affecting the current of air as it passes in expiration from the larynx through the mouth. If the vocal cords are called into action, and the sounds thus produced are modified by the muscular movements of the tongue, cheek and lips, we have vocal speech; but if the glottis is widely open and the vocal cords relaxed the current of air may still be moulded by the muscular apparatus so as to produce speech without voice, or whispering (see VOICE). In both cases, however, the mechanism is very complicated, requiring a series of nervous and muscular actions, all of which must be executed with precision and in accordance. In vocal speech, for example, it is necessary that the respiratory movements, more especially those of expiration, occur regularly and with nice adjustment to the kind of articulate expression required; that the vocal cords be approximated and tightened by the muscles of the larynx acting with delicate precision, so as to produce the sound of the pitch desired; that the *rima glottidis* (or aperture of the larynx) be opened so as to produce prolonged sounds, or suddenly closed so as to cut off the current of air; that the movements of the muscles of the tongue, of the soft palate, of the jaws, of the cheeks and of the lips occur precisely at the right time and to the requisite extent; and finally that all of these muscular adjustments take place with rapidity and smoothness, gliding into each other without effort and without loss of time. Exquisite co-ordination of muscular movement is therefore necessary, involving also complicated nervous actions. Hence is it that speech is acquired by long and laborious effort. A child possesses voice from the beginning; it is born with the capacity for speech; but articulate expression is the result of education. In infancy, not only is knowledge acquired of external objects, and signs attached in the form of words to the ideas thus awakened, but the nervous and muscular mechanisms by which these signs or words receive vocal expression are trained by long practice to work harmoniously.

It is not surprising, therefore, that in certain cases, owing to some obscure congenital defect, the co-ordination is not effected with sufficient precision, and that stammering is the result. Even in severe cases no appreciable lesion can be detected either in the nervous or muscular mechanisms, and the condition is similar to what may affect all varieties of finely co-ordinated movements. The mechanism does not work smoothly, but the pathologist is unable to show any organic defect. Thus the co-ordinated movements necessary in writing are disturbed in scrivener's palsy, and the skilful performer on the piano or on any instrument requiring minute manipulation may find that he is losing the power of delicate adjustment. Stammering is occasionally hereditary. It rarely shows itself before the age of four or five years, and as a rule it is developed between this age and puberty. Men stammer in a much larger proportion than women. It may occur during the course of nervous affections, such as hysteria, epilepsy or locomotor ataxia; sometimes it follows febrile disorders; often it develops in a child in a feeble state of health, without any special disease. In some cases a child may imitate a stammerer and thus acquire the habit. Any general enfeeblement of the health, and especially nervous excitement, aggravates the condition of a confirmed stammerer.

Stammerers, as a rule, find the explosive consonants *b*, *p*, *d*, *t*, *k* and hard *g* the most difficult to articulate, but many also are unable easily to deal with the more continuous consonants, such as *v*, *f*, *th*, *s*, *z*, *sh*, *m*, *n*, *y*, and in severe cases even the vowels may cause a certain amount of spasm. Usually the defect is not observed in whispering or singing; but there are exceptions to this statement. In pronouncing the explosive sounds the part of the oral apparatus that ought suddenly to open or close remains spasmodically closed, and the stammerer remains for a moment voiceless or strives pitifully to overcome the obstruction, uttering a few successive puffs or sounds like the beginning of the sound he wishes to utter. The lips thus remain closed at the attempted utterance of *b* and *p*; the tip of the tongue is pressed against the hard palate or the back of the upper front teeth in *d* and *t*; and the back of the tongue presses against the posterior part of the palate in pronouncing *g* hard and *k*. In attempting the continuous consonants, in which naturally the passage is not completely obstructed, the stammerer does not close the passage spasmodically, but the parts become fixed in the half-opened condition, or there are intermittent attempts to open or close them, causing either a drawling sound or coming to a full stop. In severe cases, where even vowels cannot be freely uttered, the spasm appears to be at the *rima glottidis* (opening of the larynx). Again, in some cases, the spasm may affect the respiratory muscles, giving rise to a curious barking articulation, in consequence of spasm of the expiratory muscles, and in such cases the patient utters the first part of the sentence slowly, gradually accelerates the speed, and makes a rush towards the close. In the great majority of cases the spasm affects the muscles of articulation proper, that is, those of the pharynx, tongue, cheeks and lips.

A condition named *aphthongia* is particularly distressing. It totally prevents speech, and may, at intervals, come on when the person attempts to speak; but fortunately it is only of temporary duration, and is usually caused by exceptional nervous excitement. It is characterized by spasm of the muscles supplied by the hypoglossal nerve, including the sterno-hyoid, sterno-thyroid and thyro-hyoid muscles. In almost all cases of stuttering it is noticed that the defect is most apparent when the person is obliged to make a sudden transition from one class of sounds to another, and the patient soon discovers this for himself and chooses his words so as to avoid dangerous muscular combinations. When one considers the delicate nature of the adjustments necessary in articulate speech, this is what may be expected. It is well known that a quickly diffusible stimulant, such as alcohol, temporarily removes the difficulty in speech.

Stuttering may be successfully overcome in some cases by a careful process of education under a competent tutor. Not a few able public speakers were at first stutterers, but a prolonged course of vocal gymnastics has remedied the defect. The patient should be encouraged to read and speak slowly and deliberately, carefully pronouncing each syllable, and when he feels the tendency to stammer, he should be advised to pause for a short time, and then by a strong voluntary effort to attempt to pronounce the word. He should also be taught how to regulate respiration during speech, so that he may not fail from want of breath. In some cases aid may be obtained by raising the voice towards the close of the sentence. Sounds or combinations of sounds that present special difficulties should be made the subject of careful study, and the defect may be largely overcome by a series of graduated exercises in reading. The practice of intoning is useful in many cases; and many persons who habitually stutter in conversation show no sign of the defect when they come to sing. In ordinary conversation it is often important to have some one present who may by a look put the stammerer on his guard when he is observed to be talking too quickly or indistinctly. Thus by patience and determination many stammerers have so far overcome the defect that it can scarcely be noticed in conversation; but even in such cases mental excitement or slovenly inattention to the rules of speech suitable for the condition may cause a relapse. In very severe cases, where the spasmodic seizures affect other muscles than those of articulation, special medical treatment is necessary, as such are on the borderland of serious nervous disturbance. All measures tending to improve the general health, the removal of any affection of the mouth or gums that may aggravate habitual stammering, the avoidance of great emotional excitement, a steady determination to overcome the defect by voluntary control, and a system of education such as has been sketched will do much in the great majority of cases to remedy stammering.

STAMP (from "to stamp," to strike or tread heavily, hence to impress, O. Eng. *stempen*, Du. *stampen*, Ger. *stampfen*, whence, O. Fr. *estamper*, mod. *étamper*), an instrument for crushing or pounding or for making impressions or marks on other bodies; thus, in mining, the stamp is that part of the machinery of a mill which crushes the ore to the fineness necessary for the separation of the valuable portions; in coining, &c., it is an engraved block or die by which the mark is impressed, hence in the most general sense of the word an impression or mark made with a "stamp," and particularly such a mark impressed on a document for purposes of certification, validity and the like, or as showing that certain duties or charges have been paid. For the first class, viz., stamps for purposes of taxation, see *Stamp Duties* below; For the second class, of which the most familiar are the small adhesive pieces of paper used as the sign that postal charges have been duly paid on letters, parcels, &c., transmitted by the postal service of a country, see POST AND POSTAL SERVICE and PHILATELY.

Stamp Duties.—The stamp duty is a tax imposed upon a great variety of legal and other documents, and forms a branch of the national revenue. The stamp is a cheap and convenient mode of certifying that the revenue regulations have been complied with. Stamp duties appear to have been invented by the Dutch in 1624. They were first imposed in England by an act of 1694 as a temporary means of raising funds for carrying on the war with France. Stamp duties in the United Kingdom form part of the inland revenue, and are placed under the control of the commissioner of inland revenue. The principal acts in force on the subject are the Stamp Act 1891 and the Stamp Duties Management Act 1891. Amendments of the law are also included in the Customs and Inland Revenue Act 1893, the Finance Acts of subsequent years, and the Revenue Act 1898. The death duties, the corporation duty, the duties on patent medicines and playing cards, and postage duties, are also technically "stamp duties"; but in ordinary use the expression is limited to those imposed on the various classes of legal instruments, such as conveyances, leases, transfers, mortgages, bonds, &c., on bills of exchange, promissory notes, contract notes, bank notes and bankers' drafts, receipts, insurance policies, bills of lading, and a few other documents. Stamps are either adhesive or impressed. The adhesive stamps, which can only be used for certain documents, can be obtained at inland revenue offices throughout the United Kingdom, and at all post offices which are money order offices. Stamps can only be impressed at the inland revenue offices in certain of the larger towns. For duties not exceeding 2s. 6d. the adhesive inland revenue or postage stamps may (in most cases) be used indiscriminately. This arrangement was first introduced in 1881, when it was applied to the penny stamp, and it has since been extended to other denominations. The commissioners of inland revenue are authorized to make allowance under certain conditions for stamps which have been inadvertently spoiled or rendered useless for their intended purposes. In order to obtain such allowance the parties must present the stamps within two years from the time when they became useless. The commissioners may be required by any person to express their opinion as to the amount of duty, if any, which is chargeable on any instrument; and such person, if dissatisfied with the assessment made, may appeal to the courts.

The stamp duty on the transfer of certain kinds of securities can be commuted by the payment of a lump sum or (in some cases) an annual composition, and the transfers then become exempt from duty.

Stamp duties are either fixed, such as the duty of one penny on every cheque irrespective of its amount, or *ad valorem*, as the duty on a conveyance, which varies according to the amount of the purchase money. The duty is denoted generally by an impressed, less frequently by an adhesive, stamp, sometimes by either at the option of the person stamping. Thus an inland bill of exchange (unless payable on demand) must have an impressed stamp, a foreign bill of exchange an adhesive stamp, while an agreement or receipt stamp may be of either kind. It should be noticed that certain documents falling within a class which as a rule is subject to stamp duty are for reasons of public policy or encouragement of trade exempted from the duty by special legislation. Examples of such documents are Bank of England notes, agreements within § 17 (but not those within § 4) of the Statute of Frauds (see FRAUD), agreements between a master of a ship and his crew, transfers of ships or shares in ships, indentures of apprenticeship for the sea service, petitions forwarded by post to the Crown or a House of Parliament and most instruments relating to the business of building and friendly societies.

As a general rule a document must be stamped at the time of execution, or a penalty (remissible by the commissioners of inland revenue) is incurred. The penalty is in most cases £10, sometimes much more; in the case of policies of marine insurance it is £100. Some instruments cannot be stamped at all after execution, even with payment of the penalty. Such are bills of exchange and promissory notes (where an impressed stamp is necessary), bills of lading, proxies for voting at meetings of proprietors of joint-stock companies and receipts after a month from date. An unstamped instrument cannot be pleaded or given in evidence except in criminal proceedings or for a collateral purpose. If an instrument chargeable with duty be produced as evidence in a court, the officer whose duty it is to read the instrument is to call the attention of the judge to any omission or insufficiency of the stamp, and if the instrument is one which may legally be stamped after execution, it may, on payment of the amount of the unpaid duty and the penalty payable by law, and a further sum of £1, be received in evidence, saving all just exceptions on other grounds. The rules of the supreme court, 1883 (Ord. xxxix. r. 8, re-enacting a provision of the Common Law Procedure Act), provide that a new trial is not to be granted by reason of the ruling of a judge that the stamp upon any document is sufficient or that the document does not require a stamp. The stamp upon a document subject to the stamp laws of a foreign state is usually admissible in evidence in a court of the United Kingdom if it conform in other respects to the rules governing the admissibility of such documents, even though it be improperly stamped according to the law of the foreign country. The admissibility of documents belongs to the *ordinatoria litis* rather than the *decisoria litis*, and is governed by the *lex fori* rather than the *lex loci contractus*, unless indeed that law makes a stamp necessary to the validity of the instrument. Certain offences, such as forging a die or stamp, selling or using a forged stamp, &c., are made felonies punishable with penal servitude for life as a maximum.

United States.—The subject of stamp duties is of unusual historical interest, as the passing of Grenville's Stamp Act of 1765 (see UNITED STATES: *History*) directly led to the American War of Independence. The act was, indeed, repealed the next year as a matter of expediency, but an act of the same year dealing with the dependency of American colonies declared the right of the British legislature to bind the colonies by its acts. The actual yield of the stamp duties under the act of 1765 was, owing to the opposition in the American colonies, only £4000—less than the expenses of putting the act into force. The stamp duties of the United States are now under the superintendence of the commissioner of internal revenue.

STANCHION (Fr. *étançon*, a wooden post), an architectural term applied to the upright iron bars in windows which pass through the eyes of the saddle bars or horizontal irons to steady the lead lights. The French call the latter *traverses*, the stanchions *montants*, and the whole arrangement *armature*. Stanchions frequently finish with ornamental heads forged out of the iron.

STANDARD, a term with three main meanings: (1) an ensign or flag; (2) a fixed weight, measure, value or quality established by law or customarily recognized as a unit of comparison by which the correctness of others can be determined; (3) an upright or standing object, such as a large candelabrum, or, particularly, a fruit-tree which stands without support. With regard to the derivation, the word which appears in most European languages, *e.g.* Du. *standaard*, Ger. *Standarte*, O. Fr. *estandart*, *estendard*, mod. *étendard*, Ital. *stendale*, *stendardo*, &c., is to be referred to the Teut. *standan*, to stand, and refers to the fixed pole to which an object or a pole was attached. The "standard" as a military ensign was properly stationary and served as the signal of the position of its owner on the ordered field of battle. The O. Fr. form *estendard* points to the influence of Lat. *extendere*, to spread out, extend, of the flag when hung upon the pole (see further FLAG for the various meanings of the word and its history). The use of the term for a recognized unit of comparison is due probably to the fact that it is something fixed or set up, stable, and not to any fanciful reference to the ensign or flag as the object to which one turns as a rallying-point. For the standard weights and measures see WEIGHTS AND MEASURES and STANDARDS DEPARTMENT below. There are many other standards, such as electrical standards (see ELECTRICITY), standard solutions in chemistry (*q.v.*) for the purpose of volumetric analysis, &c. In engineering, the component parts of machines or other structures are "standardized" in accordance with agreed measurements. For "standard time" see TIME, STANDARD.

STANDARD, BATTLE OF THE, a name given to the battle of the 22nd of August 1138 near Northallerton, in which the Scottish army under King David was defeated by the English levies of Yorkshire and the north Midlands, who arrayed themselves round a chariot carrying the consecrated banners of St Peter of York, St John of Beverley, St Wilfrid of Ripon and St Cuthbert of Durham.

See C. Oman, *Art of War: Middle Ages*, pp. 389 sqq

STANDARDS DEPARTMENT, a department of the English Board of Trade, having the custody of the imperial standards of weights and measures. As far back as can be traced, the standard weights and measures, the primary instruments for determining the justness of all other weights and measures used in the United Kingdom, were kept at the exchequer, and the duties relating to these standards were imposed upon the chamberlains of the exchequer. The office of chamberlains was abolished in 1826, under the operation of 23 Geo. III. c. 82, passed in 1783, but the custody of the standards and any duties connected therewith remained attached to an officer in the exchequer (*q.v.*) until that department was abolished in 1866. Meanwhile, in pursuance of recommendations of Standard Commissions of 1841 and 1854 and a House of Commons Committee of 1862, the Standards of Weights, Measures and Coinage Act 1866 was passed. This act created a special department of the Board of Trade, called the "Standard Weights and Measures Department," and a head of that department styled the "Warden of the Standards." His duty was to conduct comparisons, verifications and operations with reference to the standards in aid of scientific research and otherwise. The first—indeed, the only real holder—of the office was Henry Williams Chisholm (1809–1901), previously chief clerk of the old exchequer, under whose direction the department was organized; and before his retirement in 1877 it embraced not merely the re-verification of the imperial standards, but the making of local standards for local authorities, the re-verification of standards and instruments for all parts of the United Kingdom and colonies, for foreign countries which did not possess standardizing departments, the verification of manufacturers' standards and instruments, gas-measuring standards, apparatus for determining the flash-point of petroleum, &c. The Weights and Measures Act of 1878 left out all reference to the title and office of warden of the standards, and this opportunity was taken, in the words of the then permanent secretary of the Board of Trade, T. H. (afterwards Lord) Farrer, to make the office "more strictly a department of the Board of Trade." It was put in charge of an officer (Mr H. J. Chaney) termed "Superintendent of Weights and Measures," but on his death in 1906 an attempt was made partially to restore dignity and importance to the office by the appointment of Major P. A. MacMahon, F.R.S., with the title of "Deputy Warden of the Standards."[1]

There are Standards departments under the charge of experienced scientists in Berlin, St Petersburg, Paris, Vienna, Rome, Madrid, Lisbon, Brussels, Bucharest and Constantinople and at Ottawa, Melbourne and Sidney. The United States Bureau of Standards is in the department of Commerce and Labor. It was established in 1901 and is under the charge of a director. Its work follows that of the English department and embraces also research in the domain of physics, extending from chemistry on the one side to engineering on the other. It also tests and investigates standards and methods of constructing measuring-instruments for scientific societies, educational institutions, manufacturers and others.

STANDERTON, a town of the Transvaal, 114 m. S.E. of Johannesburg, on the railway from that city, via Newcastle to Durban, distant 369 m. Pop. (1904), 4589, of whom 2136 were white. Standerton is 5025 ft. above the sea and is built on the north bank of the Vaal, here spanned by two fine bridges. It is the chief town of a district of the same name and the centre of an important agricultural and pastoral region. A government stud farm is maintained here. In the neighbourhood are coal-fields. The name of the town is derived from that of the former owner of the site, an Adrian Stander, who fought against the British at Boomplaats in 1848. The town was laid out in 1870. Since 1903 it has been governed by a municipality.

STANDISH, MILES, or MYLES (*c.* 1584–1656), American colonist, was born about 1584 in Lancashire, probably of the

[1] The act of 1878, which repealed the act of 1866, merely declared that the Board of Trade should have all powers and perform all duties relative to the standards vested in or imposed upon the warden of the standards by the act of 1866 or otherwise, and the title "deputy warden of the standards" is therefore a departmental creation.

Duxbury Hall branch of the family. Nothing definite is known of him before 1620, when with his wife, Rose (d. 1621), he emigrated to New England in the "Mayflower." He became the military leader of the Plymouth colony; was sent to London in 1625 on an unsuccessful mission to secure the intervention of the Council for New England in the affairs of the colony; and in 1628 was one of the eight members of the colony who pledged themselves to pay £1800 and thus buy out the merchant adventurers. In 1631 with William Brewster and others he settled at Duxbury, where he died on the 3rd of October 1656, and where on "Captain's Hill," near the site of his home, there is a monument to him, consisting of a stone shaft, 110 ft. high, and a bronze statue of him. Longfellow's *Courtship of Miles Standish* apparently has no basis in fact; Standish's second wife, Barbara, a sister of Rose, must have been summoned to Plymouth a year before the marriage of John Alden to Priscilla Mullins. Lowell's *Interview with Miles Standish* misrepresents him: he was not a typical Puritan.

See William Bradford's *History of Plimouth Plantation.* Tudor Jenks's *Captain Myles Standish* (New York, 1905) and Henry Johnson's *Exploits of Myles Standish* (New York, 1897) are popular sketches.

STANFIELD, WILLIAM CLARKSON (1794–1867), English marine painter, was born of Irish parentage at Sunderland in 1794. As a youth he was a sailor, and during many long voyages he acquired that intimate acquaintance with the sea and shipping which was admirably displayed in his subsequent works. In his spare time he diligently occupied himself in sketching marine subjects, and so much skill did he acquire that, after having been incapacitated by an accident from active service, he received an engagement, about 1818, to paint scenery for the "Old Royalty," a sailor's theatre in Wellclose Square, London. Along with David Roberts he was afterwards employed at the Cobourg theatre, Lambeth; and in 1826 he became scene-painter to Drury Lane theatre, where he executed some admirable work, especially distinguishing himself by the production of a drop-scene, and by decorations for the Christmas pieces for which the house was celebrated. Meanwhile he had been at work upon some easel pictures of small dimensions, and was elected a member of the Society of British Artists. Encouraged by his success at the British Institution, where in 1827 he exhibited his first important picture—"Wreckers off Fort Rouge"—and in 1828 gained a premium of 50 guineas, he before 1830 abandoned scene-painting, and in that year made an extended tour on the Continent. He now produced his "Mount St Michael," which ranks as one of his finest works; in 1832 he exhibited his "Opening of New London Bridge" and "Portsmouth Harbour"—commissions from William IV.—in the Royal Academy, of which he was elected an associate in 1832 and an academician in 1835; and until his death on the 18th of May 1867 he contributed to its exhibitions a long series of powerful and highly popular works, dealing mainly with marine subjects, but occasionally with scenes of a more purely landscape character. Among these may be named: the "Battle of Trafalgar" (1836), executed for the United Service Club; the "Castle of Ischia" (1841), "Isola Bella" (1841), among the results of a visit to Italy in 1839; "French troops Fording the Margra" (1847), "The 'Victory' Bearing the Body of Nelson Towed into Gibraltar" (1853), "The Abandoned" (1856). He also executed two notable series of Venetian subjects, one for the banqueting-hall at Bowood, the other for Trentham. He was much employed on the illustrations for *The Picturesque Annual*, and published a collection of lithographic views on the Rhine, Moselle and Meuse; and forty of his works were engraved in line under the title of "Stanfield's Coast Scenery." The whole course of Stanfield's art was powerfully influenced by his early practice as a scene-painter. But, though there is always a touch of the spectacular and the scenic in his works, and though their colour is apt to be rather dry and hard, they are large and effective in handling, powerful in their treatment of broad atmospheric effects and telling in composition, and they evince the most complete knowledge of the artistic materials with which their painter deals.

STANFORD, SIR CHARLES VILLIERS (1852–), Irish musical composer, was born in Dublin on the 30th of September 1852, being the only son of Mr John Stanford, examiner in the court of chancery (Dublin) and clerk of the Crown, Co. Meath. Both parents of the composer were accomplished amateur musicians, the father being the possessor of a splendid bass voice, and the mother a very clever pianist. Under R. M. Levey (violin), Miss Meeke, Mrs Joseph Robinson, Miss Flynn and Michael Quarry (piano), young Stanford's musical powers were trained in the early days; and Sir Robert Stewart taught him composition and organ. Various feats of precocity are recorded in an article in the *Musical Times* for December 1898. He came to London as a pupil of Arthur O'Leary and Ernst Pauer in 1862, and in 1870 won a scholarship at Queen's College, Cambridge, whence he migrated to Trinity College in 1873, and succeeded J. L. Hopkins as college organist, a post he held till 1892. His appointment as conductor of the Cambridge University Musical Society gave him great opportunities, and the fame which the society soon obtained was in the main due to Stanford's energies. Before his time ladies were not admitted into the chorus, but during his tenure of the office of conductor many most interesting performances and revivals took place. In the years 1874 to 1877 he was given leave of absence for a portion of each year in order to complete his studies in Germany, where he learnt from Reinecke and Kiel. He took the B.A. degree in 1874 and M.A. in 1878, and was given the honorary degree of Mus. D., at Oxford in 1883, and at Cambridge in 1888. He first came prominently before the public as a composer with his incidental music to Tennyson's *Queen Mary* (Lyceum, 1876); and in 1881 his first opera, *The Veiled Prophet*, was given at Hanover (revived at Covent Garden, 1893); this was succeeded by *Savonarola* (Hamburg, April, and Covent Garden, July 1884), and *The Canterbury Pilgrims* (Drury Lane, 1884). A long interval separates these from his later operas, *Shamus O'Brien*, a delightful piece of Irish dramatic writing (Opera Comique, 1896) and *Much Ado About Nothing* (Covent Garden, 1901). For the main provincial festivals, works by Stanford were commissioned as follows; "Orchestral serenade" (Birmingham, 1882); "Elegiac Ode" (Norwich, 1884); *The Three Holy Children* (Birmingham, 1885); *The Revenge* (Leeds, 1886); *The Voyage of Maeldune* (Leeds, 1889); *The Battle of the Baltic* (Hereford, 1891); *Eden* (Birmingham, 1891); *The Bard* (Cardiff, 1895); *Phaudrig Crohoore* (Norwich, 1896); *Requiem* (Birmingham, 1897); *Te Deum* (Leeds, 1898); *The Last Post* (Hereford, 1900); *Stabat Mater* (Leeds, 1907). Besides these, his music includes a few choral works of importance, such as *The Resurrection* (Cambridge, 1875); *Psalm XLVI.* (Cambridge, 1877); *Carmen Saeculare* (Jubilce Ode, 1887); "Installation Ode" (Cambridge, 1892); *East to West* (London, 1893); *Psalm CL.* (Manchester, 1887); *Mass in G* (Brompton Oratory, 1893). He was appointed professor of composition at the Royal College of Music, 1883; conductor of the Bach choir in 1885; professor of music in the university of Cambridge, succeeding Sir G. A. Macfarren, 1887; conductor of the Leeds Philharmonic Society, 1897, and of the Leeds Festival from 1901 onwards. He was knighted in 1902. His instrumental works include six symphonies, many chamber compositions, among them two string quartets; besides many songs, part-songs, madrigals, &c., and incidental music to the *Eumenides* and *Oedipus Rex* (as performed at Cambridge), as well as to Tennyson's *Becket.* His church music holds an honoured place among modern Anglican compositions; and his editions of Irish and other traditional songs are well known. In 1908 he published an interesting volume of *Studies and Memories*, a collection of contributions to reviews, &c., in past years.

STANHOPE, EARLS. James Stanhope, 1st Earl Stanhope (*c.* 1673–1721), English statesman and soldier, was the eldest son of Alexander Stanhope (d. 1707), a son of Philip Stanhope, 1st earl of Chesterfield. Educated at Eton and at Trinity College, Oxford, he accompanied his father, then British minister at Madrid, to Spain in 1690, and obtained some knowledge of that country which was very useful to him in later life. A little later, however, he went to Italy where, as afterwards in Flanders, he served as a volunteer against France, and in 1695 he secured a commission in the British army. In 1701 Stanhope entered the House of Commons, but he continued his career as a soldier and was in Spain and Portugal during the earlier stages of the War of the Spanish Succession. In 1705 he served in Spain under Charles Mordaunt, earl of Peterborough, and in 1706 he was appointed British minister in Spain, but his duties were still military as well as diplomatic, and in 1708, after some differences with Peterborough, who favoured defensive measures only, he was made commander-in-chief of the British forces in that country. Taking the offensive he captured Port Mahon, Minorca, and after a visit to England, where he took part in the impeachment of Sacheverell, he returned to Spain and in 1710 helped to win the battles of Almenara and of Saragossa, his perseverance enabling the archduke Charles to enter Madrid in September. However, at Brihuega he was overwhelmed by the French and was forced to capitulate on the 9th of December 1710. He remained a prisoner in Spain for over a year and returned to England in August 1712. He now definitely abandoned the army for politics, and became one of the leaders of the Whig opposition in the House of Commons. He had his share in establishing the house of Hanover on the throne, and in September 1714 he was appointed secretary of state for the southern department, sharing with Walpole the leadership of the House of Commons. He was mainly responsible for the measures which were instrumental in crushing the Jacobite rebellion of 1715, and he forwarded the passing of the Septennial Act. He acted as George I.'s foreign minister, and only just failed to conclude a treaty of alliance with France in 1716. In 1717, consequent on changes in the ministry, Stanhope was made first lord of the treasury, but a year later he returned to his former office of secretary for the southern department. In 1717 he was created Viscount Stanhope of Mahon and in 1718 Earl Stanhope. His activity was now shown in the conclusion of the quadruple alliance between England, France, Austria and Holland in 1718, and in obtaining peace for Sweden, when threatened by Russia and Denmark, while at home he promoted the bill to limit the membership of the House of Lords. Just after the collapse of the South Sea Scheme, for which he was partly responsible but from which he did not profit, the earl died in London on the 5th of February 1721. Stanhope married Lucy, daughter of Thomas Pitt, governor of Madras, and he was succeeded by his eldest son Philip (1717–1786), a distinguished mathematician and a fellow of the Royal Society.

Charles Stanhope, 3rd Earl Stanhope (1753–1816), statesman and man of science, son of the 2nd earl, was born on the 3rd of August, 1753, and educated under the opposing influences of Eton and Geneva, devoting himself whilst resident in the Swiss city to the study of mathematics, and acquiring from the associations connected with Switzerland an intense love of liberty. In politics he took the democratic side. As Lord Mahon he contested the city of Westminster without success in 1774, when only just of age; but from the general election of 1780 until his accession to the peerage on the 7th of March 1786 he represented through the influence of Lord Shelburne the Buckinghamshire borough of High Wycombe, and during the sessions of 1783 and 1784 he gave his support to the administration of William Pitt, whose sister, Lady Hester Pitt, he married on the 19th of December 1774. When Pitt ceased to be inspired by the Liberal principles of his early days, his brother-in-law severed their political connexion and opposed with all the impetuosity of his fiery heart the arbitrary measures which the ministry favoured. Lord Stanhope's character was without any taint of meanness, and his conduct was marked by a lofty consistency never influenced by any petty motives; but his speeches, able as they were, had no weight on the minds of his compeers in the upper chamber, and, from a disregard of their prejudices, too often drove them into the opposite lobby. He was the chairman of the "Revolution Society," founded in honour of the Revolution of 1688, the members of which in 1790 expressed their sympathy with the aims of the French republicans. He brought forward in 1794 the case of Muir, one of the Edinburgh politicians who were transported to Botany Bay; and in 1795 he introduced into the Lords a motion deprecating any interference with the internal affairs of France. In all these points he was hopelessly beaten, and in the last of them he was in a "minority of one"—a sobriquet which stuck to him throughout life—whereupon he seceded from parliamentary life for five years. He was elected a fellow of the Royal Society so early as November 1772, and devoted a large part of his income to experiments in science and philosophy. He invented a method of securing buildings from fire (which, however, proved impracticable), the printing press and the lens which bear his name and a monochord for tuning musical instruments, suggested improvements in canal locks, made experiments in steam navigation in 1795–1797 and contrived two calculating machines. When he acquired an extensive property in Devonshire, he projected a canal through that county from the Bristol to the English Channel and took the levels himself. Electricity was another of the subjects which he studied, and the volume of *Principles of Electricity* which he issued in 1779 contained the rudiments of his theory on the "return stroke" resulting from the contact with the earth of the electric current of lightning, which were afterwards amplified in a contribution to the *Philosophical Transactions* for 1787. His principal labours in literature consisted of a reply to Burke's *Reflections on the French Revolution* (1790) and an *Essay* on the rights of juries (1792), and he long meditated the compilation of a digest of the statutes. The lean and awkward figure of Lord Stanhope figured in a host of the caricatures of Sayers and Gillray, reflecting on his political opinions and his personal relations with his children. His first wife died in 1780, and he married in 1781 Louisa, daughter and sole heiress of the Hon. Henry Grenville (governor of Barbadoes in 1746 and ambassador to the Porte in 1762), a younger brother of the 1st Earl Temple and George Grenville; who survived him and died in March 1829. By his first wife he had three daughters, one of whom was Lady Hester Stanhope (*q.v.*). His youngest daughter, Lady Lucy Rachael Stanhope, eloped with Thomas Taylor of Sevenoaks, the family apothecary, and her father refused to be reconciled to her; but Pitt made Taylor controller-general of the customs, and his son was one of Lord Chatham's executors. His second wife was the mother of three sons. Lord Stanhope died at the family seat of Chevening, Kent, on the 15th of December 1816, being succeeded as 4th earl by his son Philip Henry (1781–1855), who inherited many of his scientific tastes, but is best known, perhaps for his association with Kaspar Hauser (*q.v.*).

Philip Henry Stanhope, 5th Earl Stanhope (1805–1875) English historian, better known as Lord Mahon, son of the 4th earl and his wife, the daughter of the 1st Baron Carrington, was born on the 30th of January 1805. He took his degree at Christ Church, Oxford, in 1827, and entered parliament in 1830. He was under secretary for foreign affairs for the early months of 1835, and secretary to the India Board in 1845, but though he remained in the House of Commons till 1852, he made no special mark in politics. He was chiefly interested in literature and antiquities, and in 1842 took a prominent part in passing the Copyright Act. He was a trustee of the British Museum, and in 1856 he proposed the foundation of a National Portrait Gallery; its subsequent creation was due to his executors. It was mainly due to him that in 1869 the Historical Manuscripts Commission was started. As president of the Society of Antiquaries (from 1846 onwards), it was he who called attention in England to the need of supporting the excavations at Troy. And in 1855 he founded the Stanhope essay prize at Oxford. Of his own works the most important are his *Life of Belisarius* (1829); *History of the War of Succession in Spain* (1832), largely based on the first earl's papers; *History of England from the Peace of Utrecht to the Peace of Versailles* (1836–1853); *Life of William Pitt* (1861–1862); and *History of England, comprising the reign of Queen Anne until the Peace of Utrecht* (1870). A new edition of this last work was published in 1908. The two histories and the Life of Pitt are of great importance on account of Stanhope's unique access to manuscript authorities, and they remain standard works; and though here and there he has been found to give credit for too much to Lord Chatham, his industry, clear though not brilliant style, and general impartiality in criticism, have been deservedly praised. His position as an historian was already established when he succeeded to the earldom in 1855, and in 1872 he was made an honorary associate of the Institute of France. He was president of the Literary Fund from 1863 until his death. He died on the 24th of December 1875, being succeeded as 6th earl by his son Arthur Philip (1838–1905), father of the 7th earl. His second son, Edward Stanhope (1840–1893), was a well-known Conservative politician, who filled various important offices, and was finally secretary of state for war (1886–1892).

STANHOPE, LADY HESTER LUCY (1776–1839), the eldest child of the 3rd Earl Stanhope by his first wife Lady Hester Pitt, was born on the 12th of March 1776, and dwelt at her father's seat of Chevening in Kent until early in 1800, when his excitable and wayward disposition drove her to her grandmother's house at Burton Pynsent. A year or two later she travelled abroad, but her cravings after distinction were not satisfied until she became the chief of the household of her uncle, William Pitt, in August 1803. She sat at the head of his table and assisted in welcoming his guests, gracing the board with her stately beauty and enlivening the company by her quickness and keenness of conversation. Although her brightness of style cheered the declining days of Pitt and amused most of his political friends, her satirical remarks sometimes created enemies when more consideration for the feelings of her associates would have converted them into friends. Lady Hester Stanhope possessed great business talents, and when Pitt was out of office she acted as his private secretary. She was with him in his dying illness, and some of his last thoughts were concerned with her future, but any anxiety which might have arisen in her mind on this point was dispelled through the grant by a nation grateful for her uncle's qualities of a pension of £1200 a year, dating from the 30th of January 1806, which Lady Hester Stanhope enjoyed for the rest of her days. On Pitt's death she lived in Montagu Square, London, but life in London without the interest caused by associating with the principal politicians of the Tory party proved irksome to her, and she sought relief from lassitude in the fastnesses of Wales. Whilst she remained on English soil happiness found no place in her heart, and her native land was finally abandoned in February 1810. After many wanderings she settled among the Druses on Mt Lebanon, and from this solitary position she wielded an almost absolute authority over the surrounding districts. Her control over the natives was sufficiently commanding to induce Ibrahim Pasha, when about to invade Syria in 1832, to solicit her neutrality, and this supremacy was maintained by her commanding character and by the belief that she possessed the gift of divination. Her cherished companion, Miss Williams, and her trusted medical attendant, Dr Charles Lewis Meryon (1783–1877), dwelt with her for some time; but the former died in 1828, and Meryon left Mt Lebanon in 1831, only returning for a final visit from July 1837 to August 1838. In this lonely residence, the villa of Djoun, 8 m. from Sidon, in a house "hemmed in by arid mountains," and with the troubles of a household of some thirty servants, only waiting for her death to plunder the house, Lady Hester Stanhope's strength slowly wasted away, and at last she died on the 23rd of June 1839. The dissappointments of her life, and the necessity of overawing her servants as well as the chiefs who surrounded Djoun, had intensified a temper naturally imperious. In appearance as in voice she resembled her grandfather, the first Lord Chatham, and like him she domineered over the circle, large or small, in which she was placed.

Some years after her death there appeared three volumes of *Memoirs of the Lady Hester Stanhope as related by herself in Conversations with her Physician* (Dr Meryon, 1845), and these were followed in the succeeding year by three volumes of *Travels of Lady Hester Stanhope, forming the Completion of her Memoirs narrated by her Physician*. They presented a lively picture of this strange woman's life and character, and contained many anecdotes of Pitt and his colleagues in political life for a quarter of a century before his death. See also Mrs Charles Roundell, *Lady Hester Stanhope* (1910).

STANIMAKA, a town of Bulgaria in Eastern Rumelia; on the Dérin Déré, an affluent of the Maritza, 12 m. S.S.E. of Philippopolis. Pop. (1906), 14,120. It is an important seat of the wine trade and also possesses a distillery. Sericulture is carried on under British auspices. To the south of the town are the ruins of the medieval citadel. Under its Greek name Stenimachos, the town is frequently mentioned in connexion with the Bulgarian wars from the 11th century onwards.

STANISLAU (Polish, *Stanislawow*), a town in Galicia, Austria, 87 m. S.E. of Lemberg by rail. Pop. (1900), 30,410, about half Jews. It possesses a beautiful parish church, which contains the tombs of the Potocki family. The principal industries include tanning, dyeing, tile-making, milling, the production of yeast and there is a large establishment for the manufacture of railway stock. Stanislau is an important railway junction, and has a considerable trade, principally in agricultural produce. Stanislau was founded by Stanislav Potocki (d. 1683), and has been newly rebuilt since it was devastated by a great fire in 1868.

STANISLAUS I. [LESZCZYNSKI] (1677–1766), king of Poland, born at Lemberg in 1677, was the son of Rafael Leszczynski, palatine of Posen, and Anne Catherine Jablonowska. He married Catherine Opalinska by whom he had one daughter. In 1697, as cupbearer of Poland, he signed the confirmation of the articles of election of Augustus II. In 1703 he joined the Lithuanian Confederacy, which the Sapiehas with the aid of Swedish gold had formed against Augustus, and in the following year was selected by Charles XII. to supersede Augustus. Leszczynski was a young man of blameless antecedents, respectable talents, and ancient family, but certainly without sufficient force of character or political influence to sustain himself on so unstable a throne. Nevertheless, with the assistance of a bribing fund and an army corps the Swedes succeeded in procuring his election by a scratch assembly of half a dozen castellans and a few score of gentlemen (July 2, 1704). A few months later Stanislaus was forced by a sudden inroad of Augustus to seek refuge in the Swedish camp, but finally on the 24th of September 1705 he was crowned king with great splendour, Charles himself supplying his nominee with a new crown and sceptre in lieu of the ancient regalia which had been carried off to Saxony by Augustus. The first act of the new king was to conclude an alliance with Charles XII. whereby Poland engaged to assist Sweden against the tsar. Stanislaus did what he could to assist his patron. Thus he induced Mazeppa the Cossack hetman to desert Peter at the most critical period of the war, and placed a small army corps at the disposal of the Swedes. But he depended so entirely upon the success of Charles's arms that after Poltava (1709) his authority vanished as a dream at the first touch of reality. The vast majority of the Poles hastened to repudiate him and make their peace with Augustus, and Leszczynski, henceforth a mere pensioner of Charles XII., accompanied Krassau's army corps in its retreat to Swedish Pomerania. On the restoration of Augustus, Stanislaus resigned the Polish Crown (though he retained the royal title) in exchange for the little principality of Zweibrücken. In 1716 he was saved from assassination at the hands of a Saxon officer, Lacroix, by Stanislaus Poniatowski, the father of the future king. He now resided at Weissenburg in Lorraine, and in 1725 had the satisfaction of seeing his daughter Mary become the consort of Louis XV. and queen of France. His son-in-law supported his claims to the Polish throne after the death of Augustus II. in 1733, which led to the war of the Polish Succession. On the 9th of September 1733 Stanislaus himself arrived at Warsaw, having travelled night and day through central Europe disguised as a coachman, and on the following day, despite many protests, was duly elected king of Poland for the second time. But Russia, opposed to any nominee of France and Sweden, at once protested against his election; declared in favour of the new elector of Saxony, as being the candidate of her Austrian ally; and on the 30th of June

1734 a Russian army of 20,000 under Peter Lacey, after proclaiming Augustus III. at Warsaw, proceeded to besiege Stanislaus in Danzig where he had intrenched himself with his partisans (including the primate and the French and Swedish ministers) to await the promised succour from France. The siege began in October 1734. On the 17th of March 1735 Marshal Münnich superseded Lacey, and on the 20th of May the long expected French fleet appeared in the roads and disembarked 2400 men. A week after its arrival this little army gallantly attempted to force the Russian intrenchments, but was beaten off and finally compelled to surrender. This, by the way, was the first time France and Russia met as foes in the field. On the 30th of June 1735 Danzig capitulated unconditionally, after sustaining a siege of 135 days which cost the Russians 8000 men. Stanislaus, disguised as a peasant, had contrived to escape two days before. He was first heard of again at Königsberg, whence he issued a manifesto to his partisans which resulted in the formation of a confederation on his behalf, and the despatch of a Polish envoy to Paris to urge France to invade Saxony with at least 40,000 men. In the Ukraine too, Count Nicholas Potocki kept on foot to support Stanislaus a motley host of 50,000 men, which was ultimately scattered by the Russians. In 1736 Stanislaus again abdicated the throne, but received by way of compensation the dukedom of Lorraine and Bar, which was to revert to France on his death. He settled at Lunéville, founded there the *Academia Stanislai*, and devoted himself for the rest of his life to science and philanthropy. He died in 1766 at the age of 89. Among his works may be mentioned: *Œuvres du philosophe bienfaisant* (Paris, 1763; 1866).

(London, 1897); Czarnowski (Jan Nepomucen), *Stanislaw Leszczynski in Poland* (Pol.; Warsaw, 1858); Louis Lacroix, *Les Opuscules inédites de S. L.* (Nancy, 1866); *Lettres inédites de S. L.*, ed. P. Boyé (Paris, 1901); Marchioness Des Reaulx, *Le Roi Stanislas et Marie Leszczynski* (Paris, 1895). (R. N. B.)

STANISLAUS II. AUGUSTUS [Poniatowski] (1732–1798), king of Poland, the son of Stanislaw Poniatowski, palatine of Cracow, the friend and companion of Charles XII. of Sweden. Born in 1732 he owed his advance in life to the influence of his uncles the powerful Czartoryscy, who sent him to St Petersburg in the suite of the English ambassador Hanbury Williams. Subsequently, through the influence of the Russian chancellor, Bestuzhev-Ryumin, he was accredited to the Russian court as the ambassador of Saxony. Through Williams he was introduced to the grand duchess Catherine, who was irresistibly attracted to the handsome and brilliant young nobleman, for whom she abandoned all her other lovers. Poniatowski was concerned in the mysterious and disreputable conspiracy which sought to set aside the succession of the grand duke Peter and his son Paul in favour of Catherine, a conspiracy frustrated by the unexpected recovery of the empress Elizabeth and the consequent arrest of the conspirators. Stanislaus returned to Warsaw much discredited, but nevertheless was (Sept. 7, 1764) elected king of Poland through the overwhelming influence of Catherine (she had promised him the crown as early as October 1763), and was crowned on the 25th of November, to the disgust of his uncles, who would have preferred another nephew, Prince Adam Casimir Czartoryscy, as king, but were obliged to submit to the dictation of the Russian court. The best that can be said for Stanislaus as king of Poland is that with all his romantic ideas and excellent intentions he remained from first to last the creature of circumstances. He had climbed to the throne by very slippery ways, he was dependent for a considerable part of his enormous income on the woman who had compensated him with a crown for the loss of her affections, he was detested by the nobility, who regarded him as a base-born upstart and yet had to put up with him. Thus in every way his position was most difficult; yet he tried to do his duty. In the beginning of his reign he broke away from the leading-strings of his uncles and inaugurated some useful economical reforms. After the first partition (as a result of which, by the way, his debts amounting to 7,000,000 guldens were paid by the Diet and his civil list was raised to 216,000 guldens per annum) he entered enthusiastically into the attempts of the patriots to restore the power and prosperity of their country, while the eloquent oration which he delivered before the Diet on taking the oath to defend the constitution of the 3rd of May 1791, moved the susceptible deputies to tears. But when the confederation of Targowica, with the secret support of Russia, was formed against the constitution, he was one of the first to accede to it, thus completely paralysing the action of the army which, under his younger brother Prince Joseph and Thaddeus Kosciuszko, was performing prodigies. In fact, by the end of his life, Stanislaus had become an expert in the art of " acceding " and " hedging. " Of resolute and independent action he was quite incapable; in fact, his whole career is little more than a record of humiliations. Thus in 1782 when he waited upon Catherine at Kaniow during her triumphal progress to the Crimea, she kept her ancient, grey-haired lover waiting for weeks, and while half contemptuously promising to respect the integrity of Poland, she curtly declined to be present at a supper which he had prepared for her at great cost. A few years later he was forcibly abducted by the Confederates of Bar, who did not know what to do with their captive, and allowed him to return to his court in a confused, bedraggled condition. On the outbreak of the insurrection of 1794 he was obliged to sue for his very life to Kosciuszko, and suffered the indignity of seeing his effigy expunged from the coinage a year before he was obliged to abdicate his throne. The last years of his life were employed in his sumptuous prison at St Petersburg (where he died in 1798) in writing his memoirs. Of his innumerable mistresses the most notable was Mme Lullié, the widow of an upholsterer, on whom he lavished a fortune. He also contracted a secret marriage with the countess Grabowska. Yet he was capable of the most romantic friendships, as witness his correspondence with Mme Geoffrin, whom he invited to Warsaw, where on her arrival she found rooms provided for her exactly like those she had left at Paris—the same size, the same kind of carpets, the same furniture, down even to the very book which she had been reading the evening before her departure, placed exactly as she had left it with a marker at the very place where she had left off. Stanislaus had indeed a generous heart, frequently paid the debts of his friends or of deserving scholars whose cases were brought to his notice, and was exceedingly good to the poor. He also encouraged the arts and sciences, and his Wednesday literary suppers were for some time the most brilliant social functions of the Polish capital. The best description of Stanislaus is by the Swedish minister Engeström, who was presented to him early in 1788. " The king of Poland, " he says, " has the finest head I ever saw, but an expression of deep melancholy detracts from the beauty of his countenance. . . . He is broad-shouldered, deep-chested, and of such lofty stature that his legs seem disproportionately short. . . . He has all the dazzling qualities necessary to sustain his dignity in public. He speaks the Polish, Latin, German, Italian, French and English tongues perfectly . . . and his conversation fills strangers with admiration. . . . As a grand-master of the ceremonies he would have done the honours most brilliantly. . . . Moral courage he altogether lacks and allows himself to be completely led by his *entourage,* which for the most part consists of women. "

(Stockholm, 1876); *Correspondance inédite de Stanislas Poniatowski avec Madame Geoffrin* (Paris, 1875); Jan Kibinski, *Recollections of the Times of Stanislaw Augustus* (Pol. Cracow, 1899); *Mémoires secrets et inédits de Stanislas Auguste* (Leipzig, 1862); *Stanislaw and Prince Joseph Poniatowski in the Light of their Private Correspondence,* in French, edited in Polish by Bronislaw Dembinski (Lemberg, 1904). Stanislaus's diaries and letters, which were for many years in the Russian foreign office, have been published in the *Vestnik Evropy* for January 1908. See also R. N. Bain's, *The Last King of Poland and his Contemporaries* (1909). (R. N. B.)

STANLEY (Family). This ancient and historic English family derived its name from Stanley in Leek (in the Staffordshire " moorlands "). Its first known ancestor is Adam de Stanley, brother of Liulf de Audley, ancestor of the lords Audley, who lived in the time of King Stephen. His descendant William de

Stanley acquired the forestership of Wirral, with an heiress, in 1284, and was ancestor of two brothers, Sir William and Sir John Stanley. The former married the heiress of Hooton in Wirral and was ancestor of the Stanleys of Hooton, whose baronetcy, created in 1661, became extinct in 1893. The younger brother was lieutenant of Ireland under Richard II. and Henry IV., obtained from the latter the Isle of Man in fee, built a fortified house at Liverpool, and became K.G. He married the heiress of the Lathoms, a native family who had held Lathom in thanage from the Conquest at least and Knowsley by knight-service from the 12th century. His grandson Thomas was father of the first earl of Derby (see DERBY, EARLS OF) and of Sir William Stanley of Holt, whose great wealth led to his execution for treason in 1495, and also of Sir John Stanley, ancestor of the Stanleys of Alderley, who obtained a baronetcy in 1660 and a barony in 1839.

Of the second earl's younger brothers, Sir Edward was raised to the peerage as Lord Monteagle in 1514 for his services at Flodden, but the dignity passed with an heiress to the Parkers in 1581; and Sir James was ancestor of the Stanleys of Bickerstaffe, who obtained a baronetcy in 1628 and succeeded to the earldom in 1736. Their father had married the heiress of Lord Strange of Knockyn, and was summoned in that peerage from 1482 to 1497, but did not live to inherit the earldom. His wife was a first cousin of Henry VII.'s queen.

The 4th earl was summoned as Lord Strange, in his father's lifetime, as was the 5th earl, but the barony fell into abeyance between his three daughters, who contested possession of the family estates with his brother, the 6th earl. He bought out their rights in the Isle of Man, and, by his marriage with a sister and co-heir of the 18th earl of Oxford, acquired a claim to the great chamberlainship, which he advanced in 1626 and which was renewed by their descendants. His son was summoned as Lord Strange in 1628 in the erroneous belief that the family retained the dignity, and a fresh barony of Strange was thus created. But on the death of the 10th earl (1736) this barony, with the lordship of Man and other great estates, passed to the 2nd duke of Atholl, whose heir, the present duke, holds the title. The earldom with large estates in Lancashire, passed to the heir male (see above).

Although the present wealth of the Stanleys is largely derived from the great industrial development of Lancashire, they were already a power to be reckoned with in that county and in Cheshire at the time of the Wars of the Roses, and have held a leading position ever since among English nobles. For three centuries they were in succession lords-lieutenant of Lancashire and occasionally of Cheshire as well, and they have always lived in considerable state. Lathom House, their ancient seat, in the hundred of West Derby (whence possibly the style of their earldom), was wrecked in the Civil War, and, though rebuilt by the ninth earl, was sold by his daughters. But Knowsley, with its great park, is still theirs, lying to the east of Liverpool, in which their feudal tower still stood in 1821.

See Young's *Hundred of Wirral* (Liverpool, 1909); Round's *Peerage and Pedigree* (London, 1910); County Histories of Lancashire and Cheshire, and works on the peerage *passim*. (J. H. R.)

The barony of STANLEY OF ALDERLEY was created in 1839 for Sir John Thomas Stanley, Bart. (1766–1850), of Alderley Park, Cheshire, a brother of Edward Stanley (1779–1849), bishop of Norwich and father of Arthur Penrhyn Stanley. A member of parliament and a fellow of the Royal Society, he married Maria Josepha (d. 1863), daughter of John Holroyd, 1st earl of Sheffield. Their eldest son, Edward John Stanley, 2nd baron (1802–1869), entered the House of Commons in 1831 and became under-secretary to the home department in 1841, patronage secretary to the treasury from 1835 to 1841, paymaster-general in 1841, and under-secretary for foreign affairs from 1846 to 1852. In 1848, two years before he succeeded to the barony of Stanley, he was created Baron Eddisbury of Winnington. He was president of the board of trade from 1855 to 1858, and postmaster-general from 1860 to 1866. His wife, Henrietta Maria (1807–1895), a daughter of Henry Augustus Dillon-Lee, 13th Viscount Dillon, was a remarkable woman. Before her marriage in 1826 she had lived in Florence, and had attended the receptions of the countess of Albany, the widow of Charles Edward, the Young Pretender; and in London she had great influence in social and political circles. When he was patronage secretary her husband was described by Lord Palmerston as " joint-whip with Mrs Stanley." Later in life Lady Stanley of Alderley helped to found the Women's Liberal Unionist Association, and she was a strenuous worker for the higher education of women, helping to establish Girton College, Cambridge, the Girls' Public Day School Company, and the Medical College for Women. She died on the 16th of February 1895. Her younger son, Edward Lyulph Stanley (b. 1839), who in 1903 succeeded his brother Henry Edward John (1827–1903) as 4th baron, had previously had an active career as an educationist and a Liberal politician. He was a fellow of Balliol College, Oxford, and was M.P. for Oldham from 1880 to 1885. He was for many years a member of the London School Board. In 1909 on the death of the 3rd earl of Sheffield, he inherited the barony of Sheffield, and that of Stanley of Alderley now became merged in it.

STANLEY, ARTHUR PENRHYN (1815–1881), English divine, dean of Westminster, was born on the 13th of December 1815, at Alderley in Cheshire, where his father, afterwards bishop of Norwich, was then rector. He was educated at Rugby under Arnold, and in 1834 went up to Balliol College, Oxford. After obtaining the Ireland scholarship and Newdigate prize for an English poem (*The Gypsies*), he was in 1839 elected fellow of University College, and in the same year took orders. In 1840 he travelled in Greece and Italy, and on his return settled at Oxford, where for ten years he was tutor of his college and an influential element in university life. His personal relations with his pupils were of a singularly close and affectionate nature, and the charm of his social gifts and genial character won him friends on all sides. His literary reputation was early established by his *Life of Arnold*, published in 1844. In 1845 he was appointed select preacher, and published in 1847 a volume of *Sermons and Essays on the Apostolic Age*, which not only laid the foundation of his fame as a preacher, but also marked his future position as a theologian. In university politics, which at that time wore mainly the form of theological controversy, he was a strong advocate of comprehension and toleration. As an undergraduate he had entirely sympathized with Arnold in resenting the agitation led by, but not confined to, the High Church party in 1836 against the appointment of R. D. Hampden to the regius professorship of divinity. During the long agitation which followed the publication in 1841 of Tract No. XC. and which ended in the withdrawal of J. H. Newman from the Anglican Church, he used all his influence to protect from formal condemnation the leaders and tenets of the "Tractarian" party. In 1847 he resisted the movement set on foot at Oxford against Hampden's appointment to the bishopric of Hereford. Finally, in 1850, in an article published in the *Edinburgh Review* in defence of the " Gorham judgment" he asserted two principles which he maintained to the end of his life—first, "that the so-called supremacy of the Crown in religious matters was in reality nothing else than the supremacy of law," and, secondly, "that the Church of England, by the very condition of its being, was not High or Low, but Broad, and had always included and been meant to include, opposite and contradictory opinions on points even more important than those at present under discussion."

It was not only in theoretical but in academical matters that his sympathies were on the liberal side. He was greatly interested in university reform and acted as secretary to the royal commission appointed in 1850. Of the important changes in administration and education which were ultimately carried out, Stanley, who took the principal share in drafting the report printed in 1852, was a strenuous advocate. These changes included the transference of the initiative in university legislation from the sole authority of the heads of houses to an elected and representative body, the opening of college fellowships and scholarships to competition by the removal of local and other restrictions the non-enforcement at matriculation of subscription to the Thirty-nine Articles, and various steps for increasing the usefulness and influence of the professoriate. Before the report was issued, Stanley was appointed to a canonry in Canterbury Cathedral. During his residence there he published his *Memoir* of his father (1851), and completed his *Commentary on the Epistles to the Corinthians* (1855). In the winter and spring of 1852–1853 he made a tour in Egypt and the Holy Land, the result of which was his well-known volume on *Sinai and Palestine* (1856). In 1857 he travelled in Russia, and collected much of the materials for his *Lectures on the Eastern Church* (1861). His *Memorials of Canterbury* (1855), displayed the full maturity of his power of dealing with the events and characters of past history. He was also examining chaplain to Bishop A. C. Tait, his former tutor.

At the close of 1856 Stanley was appointed regius professor of ecclesiastical history at Oxford, a post which, with the attached canonry at Christ Church, he held till 1863. He began his treatment of the subject with "the first dawn of the history of the church," the call of Abraham; and published the first two volumes of his *History of the Jewish Church* in 1863 and 1865. From 1860 to 1864 academical and clerical circles were agitated by the storm which followed the publication of *Essays and Reviews*, a volume to which two of his most valued friends, Benjamin Jowett and Frederick Temple, had been contributors. Stanley's part in this controversy may be studied in the second and third of his *Essays on Church and State* (1870). The result of his action was to alienate the leaders of the High Church party, who had endeavoured to procure the formal condemnation of the views advanced in *Essays and Reviews*. In 1836 he published a *Letter to the Bishop of London*, advocating a relaxation of the terms of clerical subscription to the Thirty-nine Articles and the Prayer-book. An act amending the Act of Uniformity, and carrying out in some degree Stanley's proposals, was passed in the year 1865. In 1862, Stanley, at Queen Victoria's wish, accompanied the prince of Wales on a tour in Egypt and Palestine.

Towards the close of 1863 he was appointed by the Crown to the deanery of Westminster. In December he married Lady Augusta Bruce, sister of Lord Elgin, then governor-general of India. His tenure of the deanery of Westminster was memorable in many ways. He recognized from the first two important disqualifications—his indifference to music and his slight knowledge of architecture. On both these subjects he availed himself largely of the aid of others, and threw himself with characteristic energy and entire success into the task of rescuing from neglect and preserving from decay the treasure of historic monuments in which the abbey is so rich. In 1865 he published his *Memorials of Westminster Abbey*, a work which, despite occasional inaccuracies, is a mine of information. He was a constant preacher, and gave a great impulse to Trench's practice of inviting distinguished preachers to the abbey pulpit, especially to the evening services in the nave. His personal influence, already unique, was much increased by his removal to London. His circle of friends included men of every denomination, every class and almost of every nation. He was untiring in literary work, and, though this consisted very largely of occasional papers, lectures, articles in reviews, addresses, and sermons, it included a third volume of his *History of the Jewish Church*, a volume on the *Church of Scotland*, another of *Addresses and Sermons* preached in America, and another on *Christian Institutions* (1881). He was continually engaged in theological controversy, and, by his advocacy of all efforts to promote the social, moral, and religious amelioration of the poorer classes and his chivalrous courage in defending those whom he held to be unjustly denounced, undoubtedly incurred much and growing odium in influential circles. Among the causes of offence might be enumerated not only his vigorous defence of one from whom he greatly differed, Bishop Colenso, but his invitation to the Holy Communion of all the revisers of the translation of the Bible, including a Unitarian among other Nonconformists. Still stronger was the feeling caused by his efforts to make the recital of the Athanasian Creed optional instead of imperative in the Anglican Church. In 1874 he spent part of the winter in Russia, whither he went to take part in the marriage of the duke of Edinburgh and the grand duchess Marie. He lost his wife in the spring of 1876, a blow from which he never entirely recovered. But in 1878 he was deeply interested by a tour in America, and in the following autumn visited for the last time northern Italy and Venice. In the spring of 1881 he preached funeral sermons in the abbey on Thomas Carlyle and Lord Beaconsfield, concluding with the latter a series of sermons preached on public occasions. In the summer he was preparing a paper on the Westminster Confession, and preaching in the abbey a course of Saturday *Lectures on the Beatitudes*. He died on the 18th of July, and was buried in Henry VII.'s chapel, in the same grave as his wife. His pall-bearers comprised representatives of literature, of science, of both Houses of Parliament, of theology, Anglican and Nonconformist, and of the universities of Oxford and Cambridge. The recumbent monument placed upon the spot, and the windows in the chapter-house of the abbey, one of them a gift from Queen Victoria, were a tribute to his memory from friends of every class in England and America.

Stanley was undoubtedly the leading liberal theologian of his time in England. Throughout his writings we see the impress, not only of his distinctive genius and of his extraordinary gifts, but also of his special views, aims and aspirations. He looked on the age in which he lived as a period of transition, to be followed either by an "eclipse of faith" or by a "revival of Christianity in a wider aspect," a "catholic, comprehensive, all-embracing Christianity" that "might yet overcome the world." He was never tired of asserting his belief "that the Christian Church had not yet presented its final or its most perfect aspect to the world"; that "the belief of each successive age of Christendom had as a matter of fact varied enormously from the belief of its predecessor"; that "all confessions and similar documents are, if taken as final expressions of absolute truth, misleading"; and that "there still remained, behind all the controversies of the past, a higher Christianity which neither assailants nor defenders had fully exhausted." "The first duty of a modern theologian" he held to be "to study the Bible, not for the sake of making or defending systems out of it, but for the sake of discovering what it actually contains." To this study he looked for the best hope of such a progressive development of Christian theology as should avert the danger arising from "the apparently increasing divergence between the intelligence and the faith of our time." He enforced the duty "of placing in the background whatever was accidental, temporary or secondary, and of bringing into due prominence what was primary and essential." In the former group Stanley would, without doubt or hesitation, have placed all questions connected with Episcopal or Presbyterian orders, or that deal only with the outward forms or ceremonies of religion, or with the authorship or age of the books of the Old Testament. Even to the question of miraculous and external evidence he would have been inclined to assign a secondary place.

The foremost and highest place, that of the "essential and supernatural" elements of religion, he would have reserved for its moral and spiritual truths, "its chief evidence and chief essence," "the truths to be drawn from the teaching and from the life of Christ," in whose character he did not hesitate to recognize "the greatest of all miracles."

With such views it was not to be wondered at that, from first to last, as has already been indicated, he never lost an opportunity of supporting a policy of width, toleration and comprehension in the Church of England. So again he was always eager to insist on the essential points of union between various denominations of Christians. He was throughout his life an unflinching advocate of the connexion between Church and State. By this he understood: (1) "the recognition and support on the part of the state of the religious expression of the faith of the community," and (2) "that this religious expression of the faith of the community on the most sacred and most vital of all its interests should be controlled and guided by the whole community through the supremacy of law." At the same time he was in favour of making the creed of the Church as wide as possible—"not narrower than that which is even now the test of its membership, the Apostles' Creed"—and of throwing down all barriers which could be wisely dispensed with to admission to its ministry. As an immediate step he even advocated the admission under due restrictions of English Nonconformists and Scottish Presbyterians, to preach in Anglican pulpits.

Apart from the great impulse which he gave to the study alike of the Bible and Church history, his influence may be said in a very true sense to colour the writings of many of those who most differ from him. The subjects to which he looked as the most essential of all—the universality of the divine love, the supreme importance of the moral and spiritual elements of religion, the supremacy of conscience, the sense of the central citadel of Christianity as being contained in the character, the history, the spirit of its divine

Founder—have impressed themselves more and more on the teaching and the preaching of every class of clergy in the Church.

See G. G. Bradley, *Recollections of A. P. Stanley* (1883); R. E. Prothero and G. G. Bradley, *Life and Correspondence of Dean Stanley* (2 vols., 1893).

STANLEY, EDWARD (1779–1849), bishop of Norwich, the younger brother of the 1st Baron Stanley of Alderley, was born in London and educated at St John's College, Cambridge (16th wrangler, 1802). He was ordained in 1802 and became rector of Alderley, Cheshire, three years later. Here he took a great interest in education, and encouraged especially the teaching of secular subjects at his school. In 1837 he was consecrated bishop of Norwich. The diocese at this time was conspicuous for laxity and want of discipline, and this he proceeded to remedy, although at first he met with much opposition. Ordinations and confirmations were held more regularly and frequently, the schools were properly inspected, the Plurality Act was enforced and undesirable clergy were removed. He was tolerant towards Dissenters and supported all missionary undertakings without regarding their sectarian associations. In politics he was a Liberal and devoted himself especially to educational questions. Dean Stanley (see above) was his third son.

Stanley's letters, *Before and after Waterloo* (edited by J. H. Adeane and M. Grenfell, 1907), are full of interest to students of Napoleonic history.

STANLEY, SIR HENRY MORTON (1840–1904), British explorer of Africa, discoverer of the course of the Congo, was born at Denbigh, Wales, on the 10th of June 1840.[1] His parents were named Rowlands or Rollant, and his father, who died in 1843, was the son of a small farmer. John Rowlands, by which name Stanley was baptized, was brought up first by his maternal grandfather, and after his death was boarded out by his mother's brothers at half a crown a week. In 1847 he was taken to the St Asaph Union workhouse, where he was noted for his activity and intelligence. The schoolmaster at the workhouse, James Francis (who eventually died in a madhouse), was a tyrant of the Squeers type, and in May 1856, Rowlands, after giving Francis a thrashing, ran away from school. He sought out his paternal grandfather—a well-to-do farmer—who refused to help him. A cousin, however, who was master of a national school at Brynford, took him in as a pupil teacher. But within a year he was sent to Liverpool, where he lived with an uncle who was in straitened circumstances. The lad, after working at a haberdasher's and then at a butcher's shop, engaged himself as a cabin boy on a sailing ship bound for New Orleans, in which city he landed early in 1859. There he obtained a situation through the good offices of a merchant named Henry Morton Stanley, who subsequently adopted the lad as his son, designing for him a mercantile career. To this end young Stanley (as he was henceforth known) was sent to a country store in Arkansas. The merchant shortly afterwards died, without having made further provision for his protégé.

When the Civil War broke out in 1861 Stanley enlisted in the Confederate army; he was taken prisoner at the battle of Shiloh (April 1862), and after two months' experience of the hardships of Camp Douglas, Chicago (where the prisoners of war were confined), he obtained release by enrolling in the Federal artillery. In less than a month he was discharged as unfit. In November 1862 he returned to Liverpool " very poor, in bad health and in shabby clothes," and made his way to Denbigh, but was turned away from his mother's door. This incident deeply affected him. Naturally of a sensitive, affectionate nature, henceforth he practised strong self-suppression and reserve. For a livelihood he took to the sea—was wrecked off Barcelona—and in August 1864 enlisted in the United States navy. According to an apparently authentic story[2] he obtained promotion for swimming 500 yds. and tying a rope to a captured steamer, while exposed to the shot and shell of a battery of ten guns. After the war he crossed the plains to Salt Lake City, Denver, and other parts, acquiring a reputation as a vivid descriptive writer for the press. Thus began a series of adventures in search of " copy." In the autumn of 1866 we hear of him travelling in Asia Minor "*en route* for Tiflis and Tibet," and as being attacked, with his two companions, by brigands, robbed and imprisoned, the Porte subsequently paying through the American minister an indemnity for the outrage. In December of the same year Stanley revisited Denbigh and St Asaph, returning thence to America. In 1867 he joined General Hancock's expedition against the Red Indians, acting as correspondent for the *Missouri Democrat* and other papers. His reports induced the *New York Herald* to send him to accompany the British expedition of 1867–68 against the emperor Theodore of Abyssinia. Succeeding in sending through the first news of the fall of Magdala, Stanley attracted the special attention of the proprietor of the *Herald*, James Gordon Bennett, and received from him a roving commission. He went to Crete, then in rebellion, in the latter part of 1868, and thence to Spain, where he arrived in time to witness the scenes following the flight of Queen Isabella from Madrid. He chronicled the events of the Republican rising in 1869 and was at Madrid in October of that year, when he received a telegram from Mr Gordon Bennett, jun., summoning him to Paris.

Arrived in Paris Stanley was informed that he was to go and find Livingstone.[3] Stanley then shared the common opinion that Livingstone had died somewhere in Central Africa, but Bennett was sure he was alive and Stanley was to find and help him to the best of his ability. The journey, which was to be kept secret to avoid suspicion, was to begin next day. Strangely enough, though so urgent in the matter, Bennett cumbered Stanley with a large number of commissions to fulfil before the quest for Livingstone could be begun. In accordance with these instructions, Stanley went to Egypt to witness the opening of the Suez Canal in November, thence to Philae, and in January 1870 he arrived in Jerusalem, where he met Captain (afterwards Sir) Charles Warren. Next, by way of Constantinople, he visited the battlefields of the Crimea, and, passing through the Caucasus from Baku, he made an adventurous journey across Persia to Bushire, whence he sailed to Bombay. From Bombay he sailed for Africa, reaching Zanzibar on the 6th of January 1871.

The journey to the interior was begun on the 21st of March; on the 10th of November, having overcome innumerable difficulties, Stanley arrived at Ujiji, where Livingstone then was; the young traveller greeting the famous veteran with the words, " Dr Livingstone, I presume?" With Livingstone Stanley navigated the northern shores of Tanganyika and settled the question as to whether the Rusizi was an effluent or an affluent—a point then much debated in connexion with the hydrography of the Nile basin. Leaving Tanganyika on the 9th of January 1872 Stanley regained Zanzibar on the 7th of May. He had accomplished his mission, and by it he established his reputation as a leader of men and an explorer of great promise. His story, made public in a picturesque narrative, *How I Found Livingstone* (1872), was at first received in London with some incredulity, owing in part to his connexion with American journalism of a type then unfamiliar and distasteful; but the journals of Livingstone, which he brought home, silenced the critics, and from Queen Victoria Stanley received a gold snuff-box set with brilliants and her thanks for the services he had rendered. Nevertheless Stanley records that all the actions of his life, and all his thoughts, since 1872, were strongly coloured by the storm of abuse and the wholly unjustifiable reports circulated about him then.

A series of public lectures in England and America followed. In 1873, as war correspondent of the *Herald*, he accompanied Wolseley's expedition to Ashanti, which he described, together with his Abyssinian experiences, in a volume entitled *Coomassie and Magdala: Two British Campaigns* (London, 1874). On reaching the island of St Vincent from Ashanti in 1874 he first heard that Livingstone was dead, and that the body was on its way to England. After the funeral of Livingstone some time was spent in negotiations for sending Stanley again to Africa,

[1] This is the usually accepted date, but from Stanley's *Autobiography* it would appear that the year of his birth was 1842.

[2] See C. Rowlands, *Henry M. Stanley*, p. 102.

[3] Previously, in November 1868, Stanley had been sent to Egypt by the *Herald* " to meet Livingstone," at the time reported to be on his way home. Stanley got as far as Aden when he was recalled.

there to determine geographical problems left unsolved by the deaths of Livingstone and Speke, and the discovery by Sir Samuel Baker of Albert Nyanza, a lake then reputed to extend illimitably in a southerly direction. Finally, Sir Edward Lawson (afterwards Lord Burnham), the editor and proprietor of the *Daily Telegraph,* to whom Stanley had communicated his desires, and Sir Edwin Arnold of that journal, induced Mr Gordon Bennett to join them in raising a fund for an Anglo-American expedition under Stanley's command. This expedition lasted from October 1874 to August 1877 and accomplished more than any other single exploring expedition in Africa. Politically, also, the journey had momentous consequences; it led directly to the foundation of the Congo State and to the partition of the hitherto unappropriated regions of Africa between the states of western Europe. Stanley started from the east coast and reached the ocean again at the mouth of the Congo, having demonstrated the identity of that river with Livingstone's Lualaba by navigating its course from Nyangwe—the point at which both Livingstone and Lovett Cameron had turned aside. This wonderful achievement was accomplished in the face of difficulties so great that they could have been overcome only by such a man as Stanley proved himself to be—a man of inflexible will, who having conceived a vast design carried it to its conclusion regardless of any obstacles, sparing neither himself nor his associates and, if opposed, prepared to shed blood to attain his object. Of the three white men who accompanied him all died during the journey; Stanley himself was prematurely aged. The discovery of the course of the Congo, though the greatest, was but one of many geographical problems solved during this memorable expedition. The part played by the Kagera in the Nile system, the unity and approximate area of Victoria Nyanza, the true length and area of Tanganyika and the whereabouts of its outlet, and the discovery of a new lake, Dweru, which at the time Stanley believed to be a branch of Albert Nyanza, are some of the other discoveries made by Stanley at this time. The story of the expedition was given at length in *Through the Dark Continent* (London, 1878). Stanley's letters from Uganda and his call for missionaries to go to the court of Mtesa met with an immediate response and proved the first step in bringing the region of the Nile sources under the protection of Great Britain. Important as was this result of his journey it was eclipsed by the events which followed his revelation of the Congo as a magnificent waterway piercing the very heart of Africa. Of the commercial possibilities of the region he had made known Stanley was well aware. The one other man who at once grasped the situation was Leopold II., king of the Belgians, who sent commissioners to intercept Stanley at Marseilles, when he was on his way back to England, with proposals to return to the Congo, proposals which Stanley, much needing rest, put aside for the time. Approached again in the summer of 1878 Stanley lent a more favourable ear to Leopold's suggestions. Efforts made by the explorer in the autumn to arouse British merchants to the importance of the Congo basin were unavailing, and in November Stanley went to Brussels and committed himself to the schemes of the king of the Belgians. A *Comité d'études du Haut Congo* was formed and Stanley was entrusted with the leadership of the new expedition, which was, in his own words, " to prove that the Congo natives were susceptible of civilization and that the Congo basin was rich enough to repay exploitation." Stanley reached the Congo in August 1879, and the work he accomplished there in the ensuing five years enabled the Comité, which had meantime changed its name to that of *Association internationale du Congo,* to obtain the recognition of America and Europe to its transformation into an independent state (" The Congo Free State ") under the sovereignty of King Leopold. Stanley described his labours in *The Congo and the Founding of its Free State* (London, 1885), a book which throws valuable light on the manner in which the promoters of that enterprise set to work, and the object at which, from the beginning, they aimed. For the political aspects of this question see AFRICA (§ 5) and CONGO FREE STATE. Here it is only necessary to indicate what Stanley actually accomplished on the Congo. At the outset the area of his activities was restricted by the enterprise of the French traveller de Brazza, who, reaching Stanley Pool by a more northern route, placed—September and October 1880—the neighbouring districts on the north bank of the Congo under French protection. De Brazza's journey was directly inspired by Stanley's discoveries, and thus early had those discoveries led to international rivalries. Notwithstanding this check Stanley, without much trouble with the natives, founded stations for his association along the banks of the river as high up as Stanley Falls. A more difficult task was the making of a road through the cataract region and the carrying over it in sections of four small steamers, all of which were launched on the middle river. This road-making exploit earned for Stanley from the natives the name of *Bula Matari,* the rock-breaker, the all-powerful—a fit description of the man who allowed no obstacles to turn him from the achievement of his purpose.

Stanley returned to Europe in the middle of 1884 and attended the Berlin Conference of 1884–1885, which dealt with African affairs, acting as technical adviser of the American plenipotentiaries. While in Germany he lectured in various cities on the benefits which would result from the opening up of Central Africa, and found the Germans more alive than the British to the great interests at stake. The revelation of what the *Association internationale* had done intensified the struggle among the powers for the possession of African territory. Stanley did not return to the Congo on the recognition of the Free State but took up his residence in London. With James F. Hatton, a leading Manchester merchant, he promoted the Royal Congo Railway Company to connect Stanley Pool with the lower river, but the scheme at the time came to nought, partly owing to the indifference of English capitalists and partly in consequence of a clause inimical to British interests in the charter which King Leopold proposed to grant the company.

Though still an American citizen Stanley's interests and ambitions were becoming distinctly British, his sympathies in that direction being joined to a personal loyalty to the king of the Belgians.[1] A desire to serve both parties was one of the leading motives in his next African adventure. Stanley had become deeply interested in the schemes of Mr (afterwards Sir) William Mackinnon, chairman of the British India Steam Navigation Company, for establishing a British protectorate in East Equatorial Africa, and it was believed that this object could be furthered at the same time that relief was afforded to Emin Pasha (*q.v.*), governor of the Equatorial Province of Egypt, who had been isolated by the Mahdist rising of 1881–1885. Stanley agreed to conduct an expedition, nominally in the service of the khedive of Egypt, for the relief of Emin. The major part of the funds needed was supplied by a committee, of which Mackinnon was chairman. Instead of choosing the direct route via Zanzibar or Mombasa, Stanley decided to go by way of the Congo, as thereby he would be able to render services to the infant Congo State, then encountering great difficulties with the Zanzibar Arabs established on the upper Congo. Stanley left Europe in January 1887 and at Zanzibar entered into an agreement with Tippoo Tib, the chief of the Congo Arabs, appointing him governor of Stanley Falls station on behalf of the Congo State, and making another arrangement with him to supply carriers for the Emin relief expedition. Stanley and Tippoo Tib travelled together up the Congo as far as Bangala, reached on the 30th of May. Thence Tippoo Tib went on to Stanley Falls and Stanley prepared for a journey to Albert Nyanza, where he expected to meet Emin. On the 15th of June Yambuya, on the lower Aruwimi, was reached, and here Stanley left his rear-guard under command of Major E. M. Barttelot and Mr J. S. Jameson. On the 28th Stanley and the advance-guard started for Albert Nyanza, " and until the 5th of December, for 160 days, we marched through the forest, bush and jungle, without ever having seen a bit of greensward of the size of a cottage chamber floor.

[1] Of the later policy pursued in the Congo State Stanley wrote, in 1896, that it was " erring and ignorant." To go back to the Congo " would be to disturb a moral malaria injurious to the reorganizer " (*Autobiography*, p. 537).

Nothing but miles and miles, endless miles of forest." Starvation, fever, the hostility of the tribes, were daily incidents of this terrible march, during which Stanley lost nearly 50% of his men. On the 13th of December Albert Nyanza was reached, and after some delay communication was opened with Emin, who came down the lake from the Nile in a steamer, the two chiefs meeting on the 29th of April 1888. Disquieted by the non-arrival of his rearguard, Stanley retraced his steps, and on the 17th of August, a short distance above Yambuya, found that Tippoo Tib had broken faith, that Barttelot had been murdered, that Jameson (who soon afterwards died of fever) was absent at Stanley Falls, and that only one European, William Bonny, was left in the camp. Collecting those who survived of the rearguard Stanley for the third time traversed the primeval forest, and in January 1889 all that was left of the expedition was assembled at Albert Nyanza. Of 646 men with whom he entered the Congo, but 246 remained. In April the return journey to Zanzibar by way of Uganda was begun, Emin reluctantly accompanying Stanley. On this homeward journey Stanley discovered Ruwenzori (the Mountains of the Moon), traced the course of the Semliki River, discovered Albert Edward Nyanza and the great south-western gulf of Victoria Nyanza. During his stay in the Congo forests he had also obtained much information concerning the pygmy tribes. As to the political results of the expedition, Stanley's proposals to Emin to hold the Equatorial Province for the Congo State or to move nearer Victoria Nyanza and enter the service of Mackinnon's British East Africa Company had not been accepted, but he concluded agreements with various chiefs in the lake regions in favour of Great Britain, agreements which were handed over to the East Africa Company. Zanzibar was reached on the 6th of December 1889 and the expedition was at an end. Stanley's account of it, *In Darkest Africa*, was published (in six languages) in 1890.

Returning to England, Stanley was received with much honour, among the many distinctions conferred upon him being the degrees of D.C.L. from Oxford and of LL.D. from Cambridge and from Edinburgh. On the 12th of July 1890 he married a lady whose graceful work as an artist was well known, Miss Dorothy Tennant, second daughter of Mr Charles Tennant, sometime M.P. for St Albans. Later in the year he visited the United States, where he made a pilgrimage to the places where his youth had been spent, and in 1891–1892 went to Australia and New Zealand on lecturing tours. On his return he was renaturalized as a British subject, and—at the solicitation of his wife—he stood at the general election in the summer of 1892 as candidate for North Lambeth in the Liberal Unionist interest, being defeated by a small majority. In 1895 he again stood for the same constituency and was elected, but he had no liking for parliamentary life, and (being also in ill-health) he did not seek re-election in 1900. In 1895 Stanley published *My Early Travels and Adventures in America and Asia*, in which he retold the story of his experiences with the Red Indians and of his eastern journey of 1869–1870. In 1897 Stanley paid his last visit to Africa. He went to the Cape as the guest of the British South Africa Company, spoke at the opening of the railway from the Cape to Bulawayo, visited the Victoria Falls of the Zambezi and had an interview with President Kruger, of whom he gives a characteristic pen-picture. One result of this journey was *Through South Africa* (1898), the last of his published works. In 1899 in recognition of his services in Africa he was made a Knight Grand Cross of the Bath. The last few years of his life were spent mainly in retirement on a small estate he had purchased, Furze Hill, near Pirbright. He died at his London residence in Richmond Terrace, Whitehall, on the 10th of May 1904. After a service in Westminster Abbey he was buried at Pirbright on the 17th of May. His widow, Lady Stanley, afterwards married, in 1907, Mr Henry Curtis, F.R.C.S. By Sir Henry Stanley she had a son, Denzil, born 1896.

In geographical discoveries Stanley accomplished more than any other explorer of Africa, with which continent his name is indissolubly connected. Notwithstanding his frequent conflicts with Arabs and negroes, he possessed in extraordinary degree the power of managing native races; he was absolutely fearless and ever ready to sacrifice either himself or others to achieve his object. His books differ widely from the ordinary books of travel. Stanley had a gift of dramatic narrative, and his power of portraiture was remarkable. Curiously, the least successful of his works was the only one which he cast in the form of fiction, *My Kalulu, Prince, King and Slave*. Another volume from his pen, *My Dark Companions and their Strange Stories* (1893), is a valuable contribution to folklore.

The Autobiography of Sir Henry Morton Stanley, ed. by his wife, Dorothy Stanley, appeared in 1909. *Henry M. Stanley, the Story of his Life* . . . (London, n.d. [1872]), by C. Rowlands, contains, notwithstanding many inaccuracies, valuable information concerning his family and early career. The following books may also be consulted: Mrs J. S. Jameson, *Story of the Rear Column of the Emin Pasha Relief Expedition* (1890); W. G. Barttelot, *The Life of Edmund Musgrave Barttelot* . . . (1890); H. Brode, *Tippoo Tib, the Story of his Career in Central Africa* (1907). (F. R. C.)

STANLEY, THOMAS (1625–1678), English poet and philosopher, son of Sir Thomas Stanley of Cumberlow, in Herts, was born in 1625. His mother, Mary Hammond, was the cousin of Richard Lovelace, and Stanley was educated in company with the son of Edward Fairfax, the translator of Tasso. He proceeded to Cambridge in 1637, in his thirteenth year, as a gentleman commoner of Pembroke Hall. In 1641 he took his M.A. degree, but seems by that time to have proceeded to Oxford. He was wealthy, married early, and travelled much on the Continent. He was the friend and companion, and at need the helper, of many poets, and was himself both a writer and a translator of verse. His *Poems* appeared in 1647; his *Europa, Cupid Crucified, Venus Vigils*, in 1649; his *Aurora and the Prince*, from the Spanish of J. Perez de Montalvan, in 1647; *Oronta, the Cyprian Virgin*, from the Italian of G. Preti (1650); and *Anacreon; Bion; Moschus; Kisses by Secundus* . . . a volume of translations, in 1651. Stanley's most serious work in life, however, was his *History of Philosophy*, which appeared in three successive volumes between 1655 and 1661. A fourth volume (1662), bearing the title of *History of Chaldaick Philosophy*, was translated into Latin by J. Le Clerc (Amsterdam, 1690). The three earlier volumes were published in an enlarged Latin version by Godfrey Olearius (Leipzig, 1711). In 1664 Stanley published in folio a monumental edition of the text of Aeschylus. He died at his lodgings in Suffolk Street, Strand, on the 12th of April 1678, and was buried in the church of St Martin-in-the-Fields. His portrait was painted by Sir Peter Lely; his wife was Dorothy, daughter and coheir of Sir James Emyon, of Flower, in Northamptonshire. Stanley is a very interesting transitional figure in English literature. Born into a later generation than that of Waller and Denham, he rejected their reforms, and was the last to cling obstinately to the old prosody and the conventional forms of fancy. He is the frankest of all English poets in his preference of decadent and Alexandrine schools of imagination; among the ancients he admired Moschus, Ausonius, and the *Pervigilium Veneris*; among the moderns, Joannes Secundus, Gongora and Marino. The English metaphysical school closes in Stanley, in whom it finds its most delicate and autumnal exponent, who went on weaving his fantastic conceits in elaborately artificial measures far into the days of Dryden and Butler. When Stanley turned to prose, however, his taste became transformed. He abandoned his decadents for the gravest masters of Hellenic thought. As an elegant scholar of the illuminative order, he secured a very high place indeed throughout the second half of the 17th century. His *History of Philosophy* was long the principal authority on the progress of thought in ancient Greece. It took the form of a series of critical biographies of the philosophers, beginning with Thales; what Stanley aimed at was the providing of necessary information concerning all "those on whom the attribute of Wise was conferred." He is particularly full on the great Attic masters, and introduces, "not as a comical divertisement for the reader, but as a necessary supplement to the life of Socrates," a blank verse translation of the *Clouds* of Aristophanes. Bentley is said to have had a very high appreciation of his scholarship, and to have made use of the poet's copious notes, still in manuscript (in the British Museum), on Callimachus.

Stanley's original poems, which had been collected in 1651, were imperfectly reprinted in Sir S. Egerton Brydges's edition of 150 copies in 1814, but never since; his "Anacreon" was issued, with the Greek text, by Mr Bullen in 1892. His prose works have not been collected. (E. G.)

STANLEY, SIR WILLIAM (1548–1630), English soldier and traitor, was the eldest son of Sir Rowland Stanley (d. 1612) of Hooton, Cheshire, a member of the famous family of that name. As a volunteer under the duke of Alva he gained his earliest military experiences in the service of Spain; then about 1570 he joined the English forces in Ireland, where he remained for fifteen years, being knighted by Sir William Drury in 1579. He was very prominent in the guerrilla warfare against the Irish rebels; he was made sheriff of Cork, and he acted as deputy for Sir John Norris, the president of Munster, where by 300 executions he terrified the inhabitants "that a man now may travel the whole country and none to molest him." Having, says William Camden, "singulari fide et fortitudine in Hibernico bello moruerat," he returned to England in October 1585, undoubtedly annoyed that his services had not been more generously rewarded. In December of this year, however, he crossed to the Netherlands with the English forces, but almost as soon as he reached his destination he was sent to Ireland to collect recruits, of whom he enlisted about 1400. Although a strong Roman Catholic, Stanley had hitherto served Elizabeth loyally, but lingering in London on his return from his Irish errand, he seems to have entered into the schemes of the Jesuits against the queen, and he was probably aware of Anthony Babington's plot. But the time for more active and personal treachery had not yet arrived, and with his Irish levies he reached Holland in August 1586, fought gallantly at Zutphen and helped Sir William Pelham to seize Deventer. In spite of some remonstrances, Stanley was made governor of this town, being given extended powers by Leicester, and his opportunity had now come. In January 1587 he surrendered Deventer to the Spaniards, and while most of his men entered the Spanish service, he travelled to Madrid to discuss the projected invasion of England, his idea being to make Ireland the base for this undertaking. These and subsequent plans were ruined by the defeat of the Armada, but he made several journeys to Spain, and did not abandon the hope that England might be invaded. In the intervals between his travels he fought under the Spanish flag in the Netherlands and in France. Later he became governor of Mechlin, and he died at Ghent on the 3rd of March 1630. His descendant, William Stanley, was created a baronet in 1661, the male line of the family becoming extinct when Sir John Stanley-Errington, the 12th baronet, died in 1893.

See R. Bagwell, *Ireland under the Tudors* (1890), vol. iii.; and J. L. Motley, *The United Netherlands* (1904), vol. ii.

STANNARD, JOSEPH (1796–1830), British painter, was born in Norwich. He there received some training in art from Robert Ladbrooke, the brother-in-law of Crome, and he also visited Holland and studied the pictures of the Dutch masters. His short life—he died when he was thirty-four—was spent in his native town, and he contributed to the exhibitions of the Norwich Society, of which he was a member, and also occasionally showed his work in London. Most of his pictures represent coast subjects or river scenes, but he had some reputation as a portrait-painter also, and in this branch of practice he achieved locally a fair measure of success. In his large picture, "The Annual Water Frolic at Thorpe," he combined landscape with portraiture. He attained no little skill as an etcher and published several plates which have a considerable degree of merit.

STANNARIES (Lat. *stannum*, Cornish, *stêan*, tin), tin mines. Stannary courts exercised a jurisdiction peculiar to Cornwall and Devon. So far as regards Cornwall the jurisdiction is an immemorial one. By ancient charters, the tinners of Cornwall were exempt from all other jurisdiction than that of the stannary courts, except in cases affecting land, life and limb. The tin-mining industry of Cornwall, dating, as it does, from the very earliest times, was always prosecuted in accordance with a particular code of customs; the earliest charter which embodies them is that of Edmund, earl of Cornwall, but the freedom then assured was rather confirmed than given for the first time, and it is impossible to say how far these customs of the stannaries courts go back. Twenty-four stannators were returned for the whole of Cornwall. Their meeting was termed a parliament, and when they assembled they chose a speaker. In earlier times, the combined tinners of Devon and Cornwall assembled on Hingston Down, a tract of highland on the Cornish side of the Tamar. After the charter of Earl Edmund, the Cornish stannators met (apparently) at Truro; those of Devonshire at Crockern Tor on Dartmoor. An officer was appointed by the duke of Cornwall or the Crown, who was lord warden of the stannaries, and the parliaments were assembled by him from time to time, in order to revise old or to enact new laws. The last Cornish stannary parliament was held at Truro in 1752. For a long series of years little or no business was transacted in the stannary courts; but the necessity for a court of peculiar jurisdiction, embracing mines and mining transactions of every description within the county of Cornwall having become more and more apparent, a committee was appointed to report on the subject, and an act of parliament was afterwards (1836) passed, suppressing the law courts of the stewards of the different stannaries, and giving to the vice-warden their jurisdiction, besides confirming and enlarging the ancient equity jurisdiction of that office. By the Stannaries Act 1855 the respective parliaments or stannaries courts of Cornwall and Devon were consolidated. From the judgments of the vice-warden an appeal lay to the lord warden, and from him to the Supreme Court. By the Stannaries Courts Abolition Act 1896 the jurisdiction of the courts was transferred to the county courts. The most important customs may be briefly stated: (*a*) "free tinners" had the right to work upon rendering the "toll-tin," usually one-fifteenth of the produce, to the owner or lord of the soil; (*b*) the right of "tin-bounding," that is, the right of bounding any unappropriated waste lands, or any several or enclosed lands which had once been waste land, subject to the custom and to the delivery of tin-toll. The bound was marked by turf or stone, and was about an acre in extent. The estate of a bounder in Devonshire is real property, but in Cornwall is personal property.

For many centuries a tax on the tin, after smelting, was paid to the earls and dukes of Cornwall. The smelted blocks were carried to certain towns (Liskeard, Lostwithiel, Penzance, Truro) to be coined, that is, a corner of the block was cut off, and the block was then stamped with the duchy seal as a guarantee of the quality. By an act of 1838 the dues payable on the coinage of tin were abolished, and a compensation was awarded to the duchy instead of them.

See T. Pearce, *Laws and Customs of the Stannaries in the Counties of Cornwall and Devon* (1725); Bainbridge, *Law of Mines and Minerals*; G. R. Lewis, *The Stanneries: a Study of the English Tin Mines* ("Harvard Economic Studies," 1908).

STANNITE, a rare mineral consisting of tin, copper and iron sulphide (a sulpho-stannate, Cu_2FeSnS_4), containing, when pure, tin 27·5, copper 29·5%. It has a metallic lustre, and, when pure, is iron-black in colour: more often, however, it is bronze-yellow, owing to tarnish or to the presence of intimately admixed chalcopyrite: for this reason it is known to miners as "bell-metal-ore" or as "tin pyrites." The hardness is $3\frac{1}{2}$ and the specific gravity 4·45. It usually occurs as granular to compact masses, rarely as crystals. Minute crystals from Bolivia have been shown to be tetragonal and hemihedral, like chalcopyrite; and to be invariably twinned, giving rise to pseudocubic forms. The mineral has been found in a number of Cornish tin mines, and was formerly worked to a limited extent as an ore. At Zinnwald in Bohemia it occurs with blende and galena, and in Bolivia with silver ores. (L. J. S.)

STANS, the capital of the eastern half (or Nidwalden) of the Swiss canton of Unterwalden. It stands amid orchards at a height of 1493 ft. above the sea-level on a plain at the north foot of the conical Stanserhorn (6238 ft). It is, by electric railway, about 2 m. from Stansstad, its port on the south shore of the lake of Lucerne, and 12 m. from Engelberg (with its great Benedictine monastery, founded about 1120), now a much-frequented summer resort, while there is also an electric railway from Stans up the Stanserhorn. In 1900 Stans had a population of 2798, all German-speaking and Romanists. Stans was the home of the Winkelried family (*q.v.*) and has a modern monument to the memory of Arnold von Winkelried, the legendary hero of the battle of Sempach (1386). In 1481 the holy Nicholas von der Flüe composed at Stans by his advice the strife between the Confederates, while in 1798 many persons were massacred here by the French. (W. A. B. C.)

STANSFELD, SIR JAMES (1820–1898), English politician, was born at Moorlands, Halifax, on the 5th of October 1820, the son of James Stansfeld, a county-court judge. Educated at University College, London, he was called to the bar in 1849. In 1847 he was introduced through his father-in-law, W. H. Ashurst, to Mazzini, with whom he formed a close friendship. In 1859 he was returned to parliament as Radical member for Halifax, which town he continued to represent for over thirty-six years. He voted consistently on the Radical side, but his chief energies were devoted to promoting the cause of Italian unity. He was selected by Garibaldi as his adviser when the Italian patriot visited England in 1862. In 1863 he moved in the House of Commons a resolution of sympathy with the Poles, and two months later was made a junior lord of the admiralty. In 1864, as the result of charges made against him by the French authorities, in connexion with Greco's conspiracy against Napoleon III., Disraeli, in the House of Commons, accused him of being "in correspondence with the assassins of Europe." Stansfeld was vigorously defended by Bright and Forster, and his explanation was accepted as quite satisfactory by Palmerston. Nevertheless he only escaped a vote of censure by ten votes, and accordingly resigned office. In 1865 he was re-elected for Halifax, and in 1866 became under-secretary of state for India. In the first Gladstone administration he held a variety of public offices, finally becoming, in 1871, the first president of the local government board. The remainder of his life was mainly spent in endeavouring to secure the repeal of the Contagious Diseases Acts, and in 1886 this object was attained. In the same year Stansfeld again became president of the local government board. He died on the 17th of February 1898.

STANTON, EDWIN M'MASTERS (1814–1869), American statesman, was born at Steubenville, Ohio, on the 19th of December 1814. He attended Kenyon College at Gambier, Ohio, from 1831 to 1833, was admitted to the bar in 1836, was prosecuting attorney of Harrison county in 1837–1839, and practised in Cadiz, O., until 1839, when he returned to Steubenville. In 1847 he removed to Pittsburg, Pennsylvania, where he took a leading place at the bar. One of his most famous cases was that of *The State of Pennsylvania* v. *The Wheeling and Belmont Bridge Company* (1849–1856), in which, as counsel for the state, he invoked successfully the aid of the Federal government in preventing the construction of a bridge over the Ohio river at Wheeling, Virginia (now West Virginia)—on the ground that the structure would interfere with the navigation of that stream by citizens of Pennsylvania. His large practice before the United States Supreme Court caused him to remove to Washington in 1856. In 1858 he was sent to California by the United States attorney-general as special Federal agent for the settlement of land claims, and he succeeded in breaking up a conspiracy by which the government would have been defrauded of vast tracts of land of almost inestimable value. Before the Civil War Stanton was a Democrat, opposed to slavery, but a firm defender of the constitutional rights of the slaveholders, and was a bitter opponent of Lincoln, whose party he then hated and distrusted. In the reorganization of President Buchanan's cabinet in 1860 Stanton became attorney-general, and he did what he could to strengthen the weak policy of the president in the last months of his administration. Although he had often violently denounced President Lincoln, the latter thought he saw in Stanton a good war minister, and in January 1862 invited him into his cabinet. In his administration of the war office Stanton was vigorous, rigid, and often harsh, and his peremptory manner, in speech and correspondence, was the cause of considerable friction between the war department and the generals, one of the last and most conspicuous instances being his controversy with General Sherman over the terms of surrender granted to J. E. Johnston's army. But he removed a horde of fraudulent contractors, kept the armies in the field well equipped, and infused energy into procrastinating generals. Not the least of his achievements was the peaceable disbandment of 800,000 soldiers at the end of the war. Remaining in the cabinet of President Andrew Johnson, Stanton exerted all his energies toward thwarting the policies of that executive, especially those related to the reconstruction of the Southern states. He expressed disapproval of the Tenure of Office Act, making the consent of the Senate necessary for the removal of civil officers, and drafted the supplementary act on Reconstruction, passed over the president's veto on the 19th of July 1867. Stanton was finally asked to resign, and on his refusal to do so the president suspended him (Aug. 12) from office and appointed General Grant (who had disapproved of the secretary's removal) secretary *ad interim*. When the Senate, however, under the terms of the Tenure of Office Act, refused (Jan. 13, 1868) to concur in the suspension, Grant left the office and Stanton returned to his duties. On the 21st of February 1868 Johnson appointed General Lorenzo Thomas secretary of war *ad interim*, and ordered Stanton to vacate, but on the same day the Senate upheld Stanton, and by way of reply the secretary made oath to a complaint against Thomas for violating the Tenure of Office Act, and invoked military protection from General Grant, who placed General E. A. Carr in charge of the war department building, while Congress came to Stanton's rescue by impeaching the president, the principal article of impeachment being that based on the removal of Stanton (see JOHNSON, ANDREW). When the impeachment proceedings failed (May 26) Stanton resigned and returned to the practice of law. In 1869 President Grant appointed him a justice of the United States Supreme Court, but he died on the 24th of December, four days after his appointment. Stanton had a violent temper and a sharp tongue, but he was courageous, energetic, thoroughly honest and a genuine patriot.

See George C. Gorham, *Life and Public Services of Edwin M. Stanton* (2 vols., Boston, 1899), and Frank A. Flower, *Edwin McMasters Stanton: The Autocrat of Rebellion, Emancipation, and Reconstruction* (New York, 1905).

STANTON, ELIZABETH CADY (1815–1902), American reformer, was born in Johnstown, New York, on the 12th of November 1815, the daughter of Daniel Cady (1773–1859), a Federalist member of the National House of Representatives in 1815–1817 and a justice of the supreme court of New York state in 1847–1855. She was educated at the Johnstown Academy and at the Troy Female Seminary (now the Emma Willard School), where she graduated in 1832. In 1840 she married Henry Brewster Stanton (1805–1887), a lawyer and journalist, who had been a prominent abolitionist since his student days (1832–1834) in Lane Theological Seminary, and who took her on a wedding journey to London, where he was a delegate to the World's Anti-Slavery Convention. He was a member of the New York Senate in 1850–1851, was one of the founders of the Republican party in New York, and from 1868 until his death was on the staff of the New York *Sun*. Mrs Stanton, who had become intimately acquainted in London with Mrs Lucretia Mott, one of the women delegates barred from the anti-slavery convention, devoted herself to the cause of women's rights. She did much by the circulation of petitions to secure the passage in New York in 1848 of a law giving a married woman property rights; and in the same year on the 19th and 20th of

June in Seneca Falls (*q.v.*), whither the Stantons had removed in 1847 from Boston, was held, chiefly under the leadership of Mrs Mott and Mrs Stanton, the first Woman's Rights Convention. She spoke before the New York legislature on the rights of married women in 1854 and on drunkenness as a ground for divorce in 1860, and for twenty-five years she annually addressed a committee of Congress urging an amendment to the Federal constitution giving certain privileges to women. With Parker Pillsbury (1809–1898) she edited in 1867–1870 *The Revolution*, a radical newspaper, which in 1870 was consolidated with the *Christian Enquirer*. To the *Woman's Tribune* she made important contributions, publishing in it serially parts of the *Woman's Bible* (1895), which she and others prepared, and her personal reminiscences, published in 1898 as *Eighty Years and More*. With Susan B. Anthony and Mathilda Joslyn Gage she wrote *The History of Woman Suffrage* (3 vols., 1880–1886). She was president of the National Woman Suffrage Association in 1865–1890. Her daughter, Harriot Stanton Blatch (1856–), also became prominent as a worker for woman's suffrage.

STANYHURST, RICHARD (1547–1618), English translator of Virgil, was born in Dublin in 1547. His father was recorder of the city, and Speaker of the Irish House of Commons in 1557, 1560 and 1568. Richard was sent in 1563 to University College, Oxford, and took his degree five years later. At Oxford he became intimate with Edmund Campian. After leaving the university he studied law at Furnival's Inn and Lincoln's Inn. He contributed in 1557 to Holinshed's Chronicles "a playne and perfecte description" of Ireland, and a history of the country during the reign of Henry VIII., which were severely criticized in Barnabe Rich's *New Description of Ireland* (1610) as a misrepresentation of Irish affairs written from the English standpoint. After the death of his wife, Janet Barnewall, in 1579, Stanyhurst went to the Netherlands. After his second marriage, which took place before 1585, with Helen Copley, he became active in the Catholic cause. He spent some time in Spain, ostensibly practising as a physician, but his real business seems to have been to keep Philip II. informed of the state of Catholic interest in England. After his wife's death in 1602 he took holy orders, and became chaplain to the archduke Albert in the Netherlands. He never returned to England, and died at Brussels, according to Wood, in 1618. He translated into English *The First Foure Bookes of Virgil his Aeneis* (Leiden, 1582), to give practical proof of the feasibility of Gabriel Harvey's theory that classical rules of prosody could be successfully applied to English poetry. The translation is an unconscious burlesque of the original in a jargon arranged in what the writer called hexameters. Thomas Nashe in his preface to Greene's *Menaphon* ridiculed this performance as his "heroicall poetrie, infired . . . with an hexameter furie . . . a patterne whereof I will propounde to your judgements. . . .

Then did he make heaven's vault to rebounde, with rounce robble hobble
Of ruffe raffe roaring, with thwick thwack thurlery bouncing."

This is a parody, but not a very extravagant one, of Stanyhurst's vocabulary and metrical methods.

His son, William Stanyhurst (1602–1663), was a voluminous writer of Latin religious works, one of which, *Dei immortalis in corpore mortali patientis historia*, was widely popular, and was translated into many languages.

Only two copies of the orginal Leiden edition of Stanyhurst's translation of Virgil are known to be in existence. In this edition his orthographical cranks are preserved. A reprint in 1583 by Henry Bynneman forms the basis of J. Maidment's edition (Edinburgh, 1836), and of Professor E. Arber's reprint (1880), which contains an excellent introduction. Stanyhurst's Latin works include *De rebus in Hibernia gestis* (Antwerp, 1584) and a life of St Patrick (1587).

STANZA (Low Lat. *stantia*, Ital. *stantia* or *stanza*), properly an apartment or storey in a house, the term being hence adopted for literary purposes to denote a complete section, of recurrent form, in a poem. A stanza is a strophe of two or more lines, usually rhyming, but always recurring, the idea of fixed repetition of form being essential to it. At the close of the 16th century the word *stanza* began to be used with an adjective to designate a particular species, as the "Spenserian stanza," because Spenser had invented that nine-lined form for his *Faerie Queen*; or "Ariosto's stanza" as Drayton described what is now known as *ottava rima*, because Ariosto had written prominently in it. By "stanzaic law" is meant the law which regulates the form and succession of stanzas. The stanza is a modern development of the strophe of the ancients, modified by the requirements of rhyme. (See VERSE; STROPHE; SPENSERIAN STANZA.)

STAPLE, a word which has had a curious and interesting development of meaning. The O. Eng. *stapul* meant a prop or support, and is to be referred to the root seen in step, stamp, &c.; the meaning is also seen in the cognate Du. *stapel*, stocks, pile, Ger. *Staffel*, step of a ladder, &c. The application, in current usage, of the word to a loop of wire or metal with two sharpened points used to fix a pin or bolt, or to fasten wire, &c., to wood, preserves the original sense. A special development in Low German of *stapel* gave the meaning of an orderly arranged heap of goods or stores, hence a store-house in which goods were arranged in a settled order, the idea of firmness or stability being that which runs through the changes of meaning to which the word has been subjected. This Low German word and sense was adapted in Old French as *estaple*, mod. *étape*, and applied to an established market or town, particularly to one which was the centre of the trade in some specific commodity. Thence the word has in modern usage been transferred to a principal or chief commodity or article of consumption.

In English economic history the term "staple" was applied to those towns which were appointed by the king as the centres for the trade of the company of the merchants of the staple. These merchants had a monopoly in the purchase and export of the staple commodities of England, viz. wool, woolfels, leather, tin and lead. The merchants of the staple were the origin of all English trading companies. The trade of the staple towns was under the management of a mayor and constables, sometimes appointed by the merchants themselves, sometimes by the mayor of the town and sometimes by the king himself. W. Stubbs (*Const. Hist.* vol. ii.) dates the growth of the system from the reign of Edward I. The monopolies of the staple were from time to time abolished and restored, but they were consolidated by a statute of 1353, the number and place of the staples being fixed, the custom declared, and the rights and privileges of the merchants confirmed. (See C. Gross, *Gild Merchants*; W. Cunningham, *Growth of English Industry and Commerce*.)

STAPLEDON, WALTER DE (1261–1326), English bishop, was born at Annery in North Devon on the 1st of February 1261. He became professor of canon law at Oxford and chaplain to Pope Clement V. and in 1307 was chosen bishop of Exeter. He went on errands to France for both Edward I and Edward II., and attended the councils and parliaments of his time. As lord high treasurer of England, an office to which he was appointed in 1320, the bishop was associated in the popular mind with the misdeeds of Edward II., and consequently, after the king fled before the advancing troops of Queen Isabella, he was murdered in London by the mob on the 15th of October 1326. Stapledon is famous as the founder of Exeter College, Oxford, which originated in Stapledon Hall, established in 1314 by the bishop and his elder brother, Sir Richard Stapledon, a judge of the king's bench. He also contributed very liberally to the rebuilding of his cathedral at Exeter.

STAR, the general term for the luminous bodies seen in the heavens; used also by analogy for star-shaped ornaments (see MEDAL; *Orders and Decorations*) or other objects, and figuratively for persons of conspicuous brilliance. The word is common to many branches of languages: in Teutonic two forms appear, *starre* or *sterre* (cf. Du. *ster*), and *sterne*, or *stern* (cf. Ger. *Stern*, and the Scand. *stjarna*, *stjerna*, &c.). From Lat. *stella*, are derived Span. and Port. *estrella*, and Fr. *étoile*.

The Greek is ἀστήρ, and the Sanskrit *tara*, for *stara*. The ultimate root is unknown, but may be connected with that meaning "to strew," and the word would thus mean the points of light scattered over the heavens. The study of the stars is coeval with the birth of astronomy (see ASTRONOMY: *History*); and among the earliest civilizations beneficent or malevolent influences were assigned to them (see ASTROLOGY). With the development of observational astronomy the sidereal universe was arbitrarily divided into areas characterized by special assemblages of stars; these assemblages were named asterisms or constellations, and each received a name suggested by mythological or other figures. The heavenly bodies fall into two classes: (1) the fixed stars, or stars proper, which retain the same relative position with respect to one another; and (2) the planets, which have motions of a distinctly individual character, and appear to wander among the stars proper.

Numerous counts of the number of stars visible to the naked eye have been made; it is doubtful whether more than 2000 can be seen at one time from any position on the earth. When a telescope is employed this number is enormously increased, and still more so with the introduction of photographic methods; with modern appliances more than a hundred million of these objects may be rendered perceptible.

Number and Magnitude of the Stars.

The recognition of stars is primarily dependent on their brightness or "magnitude"; and it is clear that stars admit of classification on this basis. This was attempted by Ptolemy, who termed the brightest stars "of the first magnitude," and the progressively fainter stars of progressively greater magnitude. Ptolemy's classification has been adopted as the basis of the more exactly quantitative modern system. In this system one star is defined to be unit magnitude higher than another if its light is less in the ratio 1:2·512. This ratio is adopted so that a difference of five magnitudes may correspond to a light-ratio of 1 : 100. This subject is treated in the article PHOTOMETRY, CELESTIAL. The faintest stars visible to the naked eye on clear nights are of about the sixth magnitude; exceptionally keen, well-trained eyes and clear moonless nights are necessary for the perception of stars of the seventh magnitude. According to E. Heis the numbers and magnitudes of stars between the north pole and a circle 35° south of the equator are:—

1st mag.	2nd mag.	3rd mag.	4th mag.	5th mag.	6th mag.
14	48	152	313	854	2010

From the value of the light-ratio we can construct a table showing the number of stars of each magnitude which would together give as much light as a first magnitude star, viz.:—

1st mag.	2nd mag.	3rd mag.	4th mag.	5th mag.	6th mag.
1	2½	6	16	40	100

Comparing these figures with the numbers of stars of each magnitude we notice that the total light emitted by all the stars of a given magnitude is fairly constant.

Variable Stars.—Although the majority of the stars are unchanging in magnitude, there are many exceptions. Stars whose brightness fluctuates are called *variable stars*. The number of known objects of this class is being added to rapidly, and now amounts to over 4000. The systematic search made at Harvard Observatory is responsible for a large proportion of the recent discoveries. Many of these stars seem to vary quite irregularly; the changes of magnitude do not recur in any orderly way. Others, however, are periodic, that is to say, the sequence of changes is repeated at regular intervals, and it is thus possible to predict when the maximum and minimum brightness will occur. Of the periodic variable stars, the lengths of the periods range from 3 hours 12 minutes, which is the shortest yet determined, to 610 days, the longest. When statistics of the lengths of the periods are collected, it is at once noticed that they fall into two fairly well-marked classes. The following table, based on S. C. Chandler's "Third Catalogue" (*Astronomical Journal*, vol. xvi.), supplemented by A. W. Roberts's list of southern variables (ibid. vol. xxi.), classifies the lengths of the periods of 330 stars.

Period in days	0 to 50	50 to 100	100 to 150	150 to 200	200 to 250	250 to 300	300 to 350	350 to 400	400 to 450	450 to 500	500 to 550	550 to 600	600 to 650
Stars	73	8	12	22	41	45	49	50	20	6	1	2	1

It will be noticed that there are very few periods between 50 and 150 days, that a considerable number are less than 50 days (actually a large majority of these are less than 10 days), and that from 150 days upwards the number of periods increases to a maximum at about 350 days and then diminishes. We thus recognize two classes of variables, of which (1) the *long-period variables* have periods ranging in general from 150 to 450 days, though a few are outside these limits, and (2) the *short-period variables* have periods less than 50 days (in the majority of cases less than 10 days). There is some over-lapping of these two classes as regards length of period, and it is doubtful in which class some stars, whose periods are between 10 days and 150 days, should be placed; but the two classes are quite distinct physically, and the variability depends on entirely different causes.

Long-period Variables.—The best known and typical star of this class is Mira or ο Ceti. This was the first variable star to be discovered, having been noticed in 1596 by David Fabricius, who thought it was a new star (a *Nova*). The varying brightness, ranging from the ninth to the second magnitude, was recognized in 1639 by John Phocylides Holwarda, and in 1667 Ismael Boulliau (1605–1694) established a periodicity of 333 days. Although the periodic outbursts of light have taken place without intermission during the two and a half centuries that the star has been under observation, they are somewhat irregular. The different maxima differ considerably in brightness; thus in 1906 (the brightest maximum since 1779) the second magnitude was reached, but in other years (as in 1868) it has failed to reach the fifth magnitude. The minima likewise are variable, but only slightly so. Also, the period varies somewhat; the maxima occur sometimes early and sometimes late as compared with the mean period, but the difference is never more than forty days. No general law has been discovered governing these irregularities. The change of magnitude takes place gradually, but the rise to maximum brilliance is rather more rapid than the decline. Spectroscopic observation shows that the increased light accompanies an actual physical change or conflagration in the star. The spectrum is of the third type with bright hydrogen emission lines (see below, *Spectra of Stars*). Stars having this type of spectrum are always variable, and a large proportion of the more recently discovered long-period variables have been detected through their characteristic spectrum.

χ Cygni is another star of this class, remarkable for its range of magnitude. In its period of 406 days it fluctuates between the thirteenth and the fourth magnitudes; thus at maximum it emits 4000 times as much light as at minimum. The mean range of 75 long-period variables observed at Harvard (*Harvard Annals*, vol. lvii.) was five magnitudes. Another variable, R Normae[1] is of interest as having a pronounced double maximum in each period.

It is natural to compare the periodic outbursts occurring in these stars with the outbursts of activity on the sun, which have a period of about eleven years. In both cases no extraneous cause can be assigned; the period seems to be inherent in the star itself and not to be determined by the revolution of a satellite (no variability of the line-of-sight motion of Mira has been found, so that it is probably not accompanied by any large companion). In both cases the rise to a maximum is more rapid than the decline to a minimum, and in fact some of the minor peculiarities of the sunspot curve are closely imitated by the light-curves of variable stars. H. H. Turner has analysed harmonically the light-curves of a number of long-period variables, and has shown that when they are arranged in a natural series the sun takes its place in the series near, but not actually at, one end. It is necessary to suppose, if the analogy is to hold, that the sun is brightest when sunspots and faculae are most numerous; this is by no means unlikely. On the other hand, the variations in the light of the sun must be very small compared with the enormous fluctuations in the light of variable stars. Moreover, the solar period (11 years) is far outside the limits of the periods of

[1] Variable stars (except those sufficiently bright to have received special names) are denoted by the capital letters R to Z followed by the name of the constellation. The first nine variables recognized in each constellation are denoted by single letters, after which combinations RR, RS, &c., are used.

variables. It is therefore perhaps misleading actually to class the sun with them; but it seems highly probable that whatever cause produces the periodic outbursts of spots and faculae on our sun differs only in degree from that which, in stars under a different physical condition of pressure and temperature, results in the gigantic conflagrations which we have been considering.

Short-period Variables.—Besides the shortness of the period these variables possess other characteristics which differentiate them from the long-period variables. The range of variation is much smaller, the difference between maximum and minimum rarely exceeding two magnitudes. Also the variations recur with perfect regularity. There is reason to believe that all the stars of this class are binary systems, and that the variations of brightness are determined by the different aspects presented by the two component stars during the period of revolution. There are several well-marked varieties of short-period variables; the most important are typified by the stars Algol, β Lyrae, ζ Geminorum and δ Cephei.

In the Algol variables one of the component stars is dark (that is to say, dark in comparison with the other), and once in each revolution, passing between us and the bright component, partially hides it. This class of variables is accordingly characterized by the fact that for the greater part of the period the star shines steadily with its maximum brilliancy, but fades away for a short time during each period. The variability of Algol (β Persei) was discovered in 1783 by John Goodricke (1764–1786), but, judging from its name, which signifies "the demon," it seems possible that its peculiarity may have been known to the ancient astronomers. Algol is ordinarily of magnitude 2·3, but once in a period of $2^{d.}\ 20^{h.}\ 49^{m.}$ it suffers partial eclipse and fades to magnitude 3·5. The duration of each eclipse is $9\frac{1}{4}$ hours. Ever since the variability of Algol was observed it was suspected to be due to a partial eclipse of the star by a dark body nearly as large as itself revolving round it; but the explanation remained merely a surmise until K. H. Vogel of Potsdam, by repeated measurements of the motion of Algol in the line of sight, showed that the star is always receding from us before the loss of light and approaching us afterwards. This leaves no room for doubt that an invisible companion passes between us and Algol about the time the diminution of light takes place, and so proves the correctness of the explanation. The dimensions of the Algol system have been calculated, with the result that Algol appears to have a diameter of 1,000,000 m. and its companion a diameter of 830,000 m.; the distance between their centres cannot be deduced without making certain doubtful assumptions, but may be about 3,000,000 m. When this distance is compared with those prevailing in the solar system, it seems an extraordinarily small separation between two such large bodies; we shall, however, presently come across systems in which the two components revolve almost or actually in contact. About 56 Algol variables were known in 1907; the variables of this class are the most difficult to detect, for the short period of obscuration may easily escape notice unless the star is watched continuously.

The variable star β Lyrae, which is typical of another class, was also discovered by Goodricke in 1784. It differs from the Algol type in having two unequal minima separated by two equal maxima. Thus in a period of $12^{d.}\ 22^{h.}$ from a maximum of magnitude 3·4 it falls to 3·9, rises again to 3·4, then falls to 4·5 and returns to magnitude 3·4. The changes take place continuously, so that there is no period of steady luminosity. The hypothesis of G. W. Myers (*Astrophysical Journal*, vol. vii.) affords at least a partial explanation of the phenomena. Two stars are supposed to revolve about one another nearly or actually in contact. In such a system the tidal forces must be very great, and under their influence the stars will not be spherical, but will be elongated in the direction of the line joining their centres. When the line of centres is at right angles to our line of sight, the stars present to us their greatest apparent surface, and therefore send us the maximum light. This happens twice in a revolution. As the line of centres becomes more oblique, the surface is seen more and more foreshortened and the brilliancy diminishes continuously. Supposing that the two stars are of unequal surface brilliancy, the magnitude at minimum will depend on which of the two stars is the nearer to us, accordingly there are two unequal minima in each revolution. When the two stars are of equal brilliancy the minima are equal; this is the case in variables of the ζ Geminorum type. When the orbits are eccentric, the tidal disturbance varying with the distance between the two components will probably cause changes in their absolute brilliancy; the variation due to change in the aspect of the system presented to us may thus be supplemented by a real intrinsic variation, both, however, being regulated by the orbital motion. A large eccentricity also produces an unsymmetrical light variation, the minimum occurring at a time not midway between two maxima; stars of this character are called Cepheid variables, after the typical star δ Cephei. All the best-known short-period variables have been proved to be binary systems spectroscopically, and to have periods corresponding with the period of light variation, so that to this extent the hypothesis we have described is well founded; but it is doubtful if it is the whole explanation. S. Albrecht has shown that, of the 10 members of the δ Cephei class for which both the orbits and the light-variations are thoroughly known, the maximum light always occurs approximately at the time when the brighter component is approaching us most rapidly; this relation, which seems to be well established, is a most perplexing one.

No hard and fast physical distinction can be drawn between the various classes of short-period variables; as the distance between the components diminishes the Algol variable merges insensibly into the β Lyrae type. The latter, on the other hand, is perhaps connected by insensible gradations with the ordinary simple star. Sir G. H. Darwin and H. Poincaré have investigated the forms taken up by rotating masses of fluid. When the angular momentum is too great for the usual spheroidal form to persist, this gives place to an ellipsoid with three unequal axes; this is succeeded by a pear-shaped form. The subsequent sequence of events cannot be traced with certainty, but it seems likely that the pear-shaped form is succeeded by an hour-glass-shaped form, which finally separates at the neck into two masses of fluid. Ellipsoidal, pear-shaped or hour-glass-shaped stars would all give rise to the phenomena of a short-period variable, and doubtless examples of these intermediate forms exist.

Certain clusters contain a remarkable number of short-period variables. Thus the cluster Messier 5 was found at Harvard to contain 185 variables out of 900 stars examined. Solon I. Bailey, on examining 63 of them, found that with one exception their periods lay between $10^{h.}\ 48^{m.}$ and $14^{h.}\ 59^{m.}$, and the range of variation between 0·7 and 1·4 magnitudes. Moreover, the light-curves were all of a uniform type, a distinctive feature of "cluster variables" being the rapid rise to a maximum and slow decline.

Temporary Stars or Novas.—From time to time a star, hitherto too faint to be noticeable, blazes out and becomes a prominent object, and then slowly fades into obscurity. According to Miss Agnes Clerke there are records of ten such stars appearing between 134 B.C. and A.D. 1500. Since that time nine novas have appeared, which have attained naked-eye visibility; and in recent years a number of very faint objects of the same class have been detected. The brightest star of all these was the famous "Tycho's star" in Cassiopeia. It was first observed on the 6th of November 1572 by Wolfgang Schuler. In five days its light had reached the first magnitude, and a little later it even equalled Venus in brilliancy and was observed in full daylight. After three weeks it began to decline, but the star did not finally disappear until March 1574. "Kepler's" nova in Ophiuchus broke out in 1604 and attained a brightness greater than that of Jupiter; it likewise gradually waned, and disappeared after about fifteen months. For nearly three centuries after these two remarkable stars no nova attained a brilliancy greater than that of the ordinary stars, until in 1901 Nova Persei appeared. This star was discovered by T. D. Anderson on the 21st–22nd of February, its magnitude at that time being 2·7. In the next two days it reached zero magnitude, thus becoming the brightest star in the northern heavens, but after that it rapidly decreased. On the 15th of March it was of the fourth magnitude; during the next three months it oscillated many times between magnitudes 4 and 6, and by the end of the year it had faded to the seventh magnitude. In July 1903 it was of the twelfth magnitude, and its light has remained constant since then. In the case of this star there is evidence that the outburst must have been extremely rapid, for the region where Nova Persei appeared had been photographed repeatedly at Harvard during February, and in particular no trace of the star was found on a plate taken on the 19th of February, which showed eleventh magnitude stars. Thus a rise of at least eight magnitudes in two days must have occurred.

On the 21st of August, six months after the discovery of Nova Persei, C. Flammarion and E. M. Antoniadi discovered that a nebula surrounded it. Subsequent photographs showed that this nebula, which consisted mainly of two incomplete rings of nebulosity, was expanding outwards at the rate of from 2″ to 3″ per day. This expansion continued at the same rate until the following year. Spectroscopic examination had already suggested prodigious velocities of the order of 1000 m. per second in the gases of the atmosphere of the nova; but the velocity implied by this expansion of the nebula was unprecedented and comparable only with the velocity of light. The suggestion was made, and seems to be the true explanation, that what was actually witnessed was the wave of light due to the outburst of the nova, spreading outwards with its velocity of 186,000 m. per second, and rendering luminous as it reached them the particles of a pre-existing nebula, whose own light had been too faint to be visible.

Two possible explanations of the phenomena of temporary stars have been held. The collision theory supposes that the outburst is the result of a collision between two stars or between a star and a swarm of meteoric or nebulous matter. The explosion theory regards the outburst as similar to the outbreak of activity of a long-period variable. Probably the latter hypothesis is the one more generally accepted now. There is one unique star, which is of special interest as occupying rather an intermediate position between a nova and a long-period variable. This is the southern star η Argus (sometimes called η Carinae). From 1750 until about 1832 it seems to have varied irregularly between the second and the fourth magnitudes. For the next ten years it slowly increased (though with slight check), and in 1843 was nearly as bright as Sirius; since then it has slowly faded, but it was not till 1869 that it ceased to be visible to the naked eye. It is now about magnitude 7·5. The slowness both of the rise and decline is in great contrast with the progress of a nova. η Argus is surrounded by a nebula, the famous "Keyhole nebula"; in this respect it resembles Nova Persei.

System of Stars.—On examining the stars telescopically, many which appear single to the unaided eye are found to be composed of two or more stars very close together. In some cases the proximity is only apparent; one star may be really at a vast distance behind the other, but, being in the same line of vision, they appear close together. In many cases, however, two or more stars are really connected, and their distance from one another is (from the astronomical standpoint) small. The evidence of this connexion is of two kinds. In a number of cases measures of the relative positions of the two stars, continued for many years, have shown that they are revolving about a common centre; when this is so there can be no doubt that they form a binary system, and that the two components move in elliptic orbits about the common centre of mass, controlled by their mutual gravitation. But these cases form a very small proportion of the total number of double stars. In many other double stars the two components have very nearly the same proper motion. Unless this is a mere coincidence, it implies that the two stars are nearly at the same distance from us. For otherwise, if they had from some unknown cause the same *actual* motion, the *apparent* motion in arc would be different. We can therefore infer that the two stars are really comparatively close together, and, moreover, since they have the same proper motion, that they remain close together. They may thus be fairly regarded as constituting a binary system, though the gravitational attraction between some of the wider pairs must be very weak.

Double Stars.

Several double stars were observed during the 17th century, ζ Ursae Majoris being the first on record. In 1784 Christian Mayer published a catalogue of all the double stars then known, which contained 89 pairs. Between 1825 and 1827 F. G. W. Struve at Dorpat examined 120,000 stars, and found 3112 double stars whose distance apart did not exceed 32″. W. S. Burnham's *General Catalogue of Double Stars* (1907) contains 13,655 pairs north of declination −31°. Undoubtedly a large number of these are only optical pairs, but mere considerations of probability show that the majority must be physically connected. For only 88 of them has it been possible as yet to deduce a period, and at least half even of these periods are very doubtful. The rates of motion are so slow that many centuries' observations are needed to determine the orbit.

The most rapid visual binary (leaving aside Capella for the moment) is δ Equulei, which completes a revolution in 5·7 years. Next to it come 13 Ceti, period 7·4 years, and κ Pegasi, period 11·4 years. From a list of systems with determined periods given by Aitken (*Lick Observatory Bulletin*, No. 84) there are 20 with periods less than 50 years, and 16 between 50 and 100 years. δ Equulei, 13 Ceti and κ Pegasi are all extremely close pairs, and can only be resolved with the most powerful instruments. Capella, whose period is only 104 days, was discovered to be double by means of the spectroscope, but has since been measured frequently as a visual binary at Greenwich. With the best instruments a star can be distinguished as double when the separation of the two components is a little less than 0·1″. From the very few orbits that have as yet been determined one interesting result has been arrived at. Most of the orbits are remarkably eccentric ellipses, the average eccentricity being about 0·5. There is a very striking relation between the eccentricity and the period of a system; in general the binaries of longest period have the greatest eccentricities. The relation applies not only to the visual but to the spectroscopic binaries; these, having shorter periods than the visual binaries, have generally quite small eccentricities. Another interesting feature is that, where the two components differ in brightness, the fainter component is often the one possessing the greater mass.

Far within the limit to which telescopic vision can extend binary systems are now being found by the spectroscope. These systems appear as a connecting link between short-period variable stars on the one hand and telescopic double stars on the other. Stars of the class to which the Algol type of variables belongs will appear to us to vary only in the exceptional case when the plane of the orbit passes so near our sun that one body appears to pass over the other and so causes an eclipse. Except when the line of sight is perpendicular to the plane of the orbit, the revolution of the two bodies will result in a periodic variation of the motion in the line of sight. Such a variation can be detected by the spectroscope. If both the bodies are luminous, especially if they do not differ much in brilliancy, the motion of revolution is shown by a periodic doubling of the lines of the spectrum; when one body is moving towards us and the other away their spectral lines are displaced (according to Doppler's principle) in opposite directions, so that all the lines strong enough to appear in both spectra appear double; when the two bodies are in conjunction, and therefore moving transversely, their spectra are merged into one and show nothing unusual. More usually, however, only one component is sufficiently luminous for its spectrum to appear; its orbital motion is then detected by a periodic change in the absolute displacement of its spectral lines. Up to 1905, 140 spectroscopic binaries had been discovered; a list of these is given in the *Lick Observatory Bulletin*, no. 79. Details of the calculated orbits of 63 spectroscopic binaries are given in *Publications of the Allegheny Observatory*, vol. i. No. 21. According to W. W. Campbell one star in every seven examined is binary.

Spectroscopic Binaries.

A continuous gradation can be traced from the most widely separated visual binaries, whose periods are many thousand years, to spectroscopic binaries, Algol and β Lyrae variables, whose periods are a few hours and whose components may even be in contact, and from these to dumb-bell shaped stars and finally to ordinary single stars. It is a legitimate speculation to suppose that these in the reverse order are the stages in the evolution of a double star. As the simple star radiates heat and contracts, it retains its angular momentum; when this is too great for the spheroidal form to persist, the star may ultimately separate into two components, which are driven farther and farther apart by their mutual tides. Tidal action also accounts for the progressively increasing eccentricities of the orbits, already referred to. This theory of the genesis of double-stars by fission is not, however, universally accepted; in particular objections have been urged by T. C. Chamberlin and F. R. Moulton. It is true that rotational instability alone is not competent to explain the separation into two components; but the existence of gravitational instability, pointed out by J. H. Jeans, enables the principal difficulties of the theory to be surmounted. Whilst there is thus no well-defined lower limit to the dimensions of systems of two stars, on the other hand we cannot set any superior limit either to the number of stars which shall form a system or to the dimensions of that system. No star is altogether removed from the attractions of its neighbours, and there are cases where some sort of connexion seems to relate stars which are widely separated in space. A curious case of this sort is that of the five stars β, γ, δ, ϵ and ζ of Ursa Major. These have proper motions which are almost identical in amount and in direction. The agreement is too close to be dismissed as a mere coincidence, and it is confirmed by a corresponding agreement of their radial motions determined by the spectroscope; and yet, seeing that β and ζ Ursae Majoris are 19° apart, these two stars must be distant from each other at least one-third of the distance of each from the sun; thus the members of this singular group are separated by the ordinary stellar distances, and probably each has neighbours, not belonging to the system, which are closer to it than the other four stars of the group. Further, E. Hertzsprung has shown that Sirius also belongs to this same system and shares its motion, notwithstanding that it is in a nearly opposite part of the sky. It is difficult to understand what may be the connexion between stars so widely separated; from the equality of their motions they must have been widely separated for a very long period.

Of multiple stars the most famous is θ Orionis, situated near the densest part of the great Orion nebula. It consists of four principal stars and two faint companions. From the more complex systems of this kind, we pass to the consideration of star-clusters, which are systems of stars in which the components are very numerous. When examined with a telescope of power insufficient to separate the individual stars, a cluster appears like a nebula. The "beehive cluster" Praesepe in Cancer is an example of an easily resolved cluster composed of fairly bright stars. The great cluster in Hercules (Messier 13), on the other hand, requires the highest telescopic power for its complete resolution into stars. Doubtless with improved telescopes many more apparent nebulae would be shown to be clusters, but there are certainly many nebulae which are otherwise constituted. Many of the clusters are of very irregular forms, either showing no well-marked centre of condensation, or else condensed in streams along certain lines. There is, however, a well-marked type to which many of the richest clusters belong; these are the *globular clusters*. They have a symmetrical circular shape, the condensation increasing rapidly towards the centre. The Hercules cluster is of this form; another example is ω Centauri, in which over 6000 stars have been counted, comprised within a circle of about 40′ diameter. These clusters present many unsolved problems. Thus Perrine, from an examination of ten globular clusters (including Messier 13 and ω Centauri), has found in each case that the stars can be separated into two classes of magnitudes. About one-third of the stars are between magnitudes 11 and 13, and the remaining two-thirds are between magnitudes 15·5 and 16·5. Stars of magnitudes intermediate between these two groups are almost entirely absent. Thus each cluster seems to consist of two kinds of stars, which we may distinguish as bright and faint; the bright stars are all approximately of one standard size, and the faint stars of another standard size and brightness.

Star-Clusters.

The question of the stability of these clusters is one of much interest. The mutual gravitation of a large number of stars crowded in a comparatively small space must be considerable, and the individual stars must move in irregular orbits under their mutual attractions. It does not seem probable, however, that they can escape the fate of ultimately condensing into one confused mass. If this surmise be correct, we are witnessing in clusters a counter-process of evolution to that which is taking place in double stars; the latter appear to be separating from a single original mass and the former condensing into one.

Colours and Spectra of Stars.—The brighter stars show a marked variety of colour in their light, and with the aid of a telescope a still greater diversity is noticeable. It is, however, only the red stars that form a clearly marked class by themselves. For purposes of precise scientific investigation the study of spectra is generally more suitable than the vague and unsatisfactory estimates of colour, which differ with different observers. Of the first magnitude red stars Antares is the most deeply coloured, Betelgeux, Aldebaran and Arcturus being successively less conspicuously red. Systematic study of red stars dates from the publication in 1866 of Schjellerup's *Catalogue*, containing a list of 280 of them.

Colours.

The two components of double stars often exhibit complementary colours. As a rule contrasted colours are shown by pairs having a bright and a faint component which are relatively wide apart; brilliant white stars frequently have a blue attendant—this is instanced in the case of Regulus and Rigel. That the effect is due to a real difference in the character of the light from the two components has been shown by spectrum analysis, but it is probably exaggerated by contrast.

The occurrence of change, either periodic or irregular, in the colour of individual stars, has been suspected by many observers; but such a colour-variability is necessarily very difficult to establish. A possible change of colour in the case of Sirius is noteworthy. In modern times Sirius has always been a typical white or bluish-white star, but a number of classical writers refer to it as red or fiery. There is perhaps room for doubt as to the precise significance of the words used; but the fact that Ptolemy classes Sirius with Antares, Aldebaran, Arcturus, Betelgeux and Procyon as "fiery red" (ὑπόκιῤῥοι) as compared with all the other bright stars which are "yellow" (ξάνθοι) seems almost conclusive that Sirius was then a redstar.

When examined with the spectroscope the light of the stars is found to resemble generally that of the sun. The spectrum consists of a continuous band of light crossed by a greater or less number of dark absorption lines or bands. As in the case of the sun, this indicates an incandescent body which might be solid, liquid, or a not too rare gas, surrounded by and seen through an atmosphere of somewhat cooler gases and vapours; it is this cooler envelope whose nature the spectroscope reveals to us, and in it the presence of many terrestrial elements has been detected by identifying in the spectrum their characteristic absorption lines. Stellar spectroscopy dates from 1862, when Sir William Huggins (with a small slit-spectroscope attached to an 8-in. telescope) measured the positions of the chief lines in the spectra of about forty stars. In 1876 he successfully applied photography to the study of the ultra-violet region of stellar spectra.

Spectra of Stars.

Various schemes of classification of spectra have been used. The earliest is that due to A. Secchi (1863–1867) who distinguished four "types"; subsequent research, whilst slightly modifying, has in the main confirmed this classification. Secchi's Type I. or "Sirian" type includes most of the bright white stars, such as Sirius, Vega, Rigel, &c.; it is characterized by strong broad hydrogen lines, which are often the only absorption lines visible. Type II. includes the "Solar" stars, as Capella, Arcturus, Procyon, Aldebaran, their spectra are similar to that of the sun, being crossed by very numerous fine lines, mostly due to vapours of metals. The great majority of the visible stars belong to these first two types. Type III. or "Antarian" stars are of a reddish colour, such as Antares, Betelgeux, Mira, and many of the long-period variables. The spectrum, which closely resembles that of a sunspot, is marked by flutings or bands of lines sharply bounded on the violet side and fading off towards the red. It has been shown by A. Fowler that these flutings are due to titanium oxide; this probably indicates a relatively low temperature, for at a high temperature all compounds would be dissociated. Type IV. also consists of red stars with banded spectra, but the bands differ in arrangement and appearance from those in the third type, and are sharply bounded on the red side. These stars are also believed to have a comparatively low surface temperature, and the bands are attributed to the presence of compounds of carbon. About 250 Type IV. stars are known, but none conspicuous; 19 Piscium, the brightest, is of magnitude 5·5.

Other classifications which are extensively used are those respectively of K. H. Vogel, J. N. Lockyer and the Draper Catalogue. The divergences depend mainly on the different views taken by their authors as to the order of stellar evolution. Apart from these considerations, the chief modification in the classification introduced by more recent investigators has been to separate Secchi's Type I. into two divisions, called *helium* and *hydrogen* stars respectively. The former are often called "Orion" stars, as all the brighter stars in that constellation with the exception of Betelgeux belong to the helium type. Helium stars are generally considered to be the hottest and most luminous (in proportion to size) of all the stars. Type II. is now subdivided into "Procyon," "Solar" and "Arcturian" stars. The "Procyon" or *calcium* stars form a transition between Type I. and Type II. proper, and show the lines of calcium besides those of hydrogen. An important variety of Type III. spectra has been recognized, in which, as well as the usual absorption bands, bright emission lines of hydrogen appear; stars having this particular spectrum are always variable. Finally, a fifth type has been added, the Wolf-Rayet stars; these show a spectrum crossed by the usual dark lines and bands, but showing also bright emission bands of blue and yellow light. About 100 Wolf-Rayet stars are known, of which γ Velorum is the brightest; they are confined to the region of the Milky Way and the Magellanic Clouds. (See PLANET.)

Evolution of Stars.—The absence of the distinctive lines of an element in the spectrum does not by any means signify that that element is wanting or scarce in the star. The spectroscope only yields information about the thin outer envelope of the star; and even here elements may be present which do not reveal themselves, for the spectrum shown depends very greatly on the temperature and pressure. Stars of the different types are therefore not necessarily of different chemical constitution, but rather are in different physical conditions, and it is generally believed that every star in the course of its existence passes through stages corresponding to all (or most of) the different types. The stars are known to be continually losing enormous quantities of energy by radiating their heat into space. Ordinary solid or liquid masses would cool very rapidly from this cause and would soon cease to shine. But a globe of gaseous matter under similar conditions will continually contract in volume, and in so doing transforms potential energy into heat. It was shown by Homer Lane that a mass of gas held in equilibrium by the mutual gravitation of its parts actually grows *hotter* through radiating heat; the heat gained by the resulting contraction more than counterbalances that lost by radiation. Thus in the first stage of a star's history we find it gradually condensing from a highly diffused gaseous state, and growing hotter as it does so. But this cannot continue indefinitely; when the density is too great the matter ceases to behave as a true gas, and the contraction is insufficient to maintain the heat. Thus in the second stage the star is still contracting, but its temperature is decreasing. The greatest temperature attained is not the same for all stars, but depends on the mass of the star. It is, however, important to bear in mind that Lane's theory is concerned with the temperature of the body of the star; the temperature of the photosphere and absorbing layers, with which we are chiefly concerned, does not necessarily follow the same law. It depends on the rapidity with which convection currents can supply heat from the interior to replace that radiated, and on a number of other nicely balanced circumstances which cannot well be calculated.

Conflicting opinions are held as to the various steps in the process of evolution and the order in which the various types succeed one another, but the following perhaps represents in the main the most generally accepted view. Starting from a widely diffused nebula, more or less uniform, we find that, in consequence of gravitational instability, it will tend to condense about a number of nuclei. Jeans has even estimated theoretically the average distances apart of these nuclei, and has shown that it agrees in order of magnitude with the observed distances of the stars from one another (*Astrophysical Journal*, vol. xxii.). As the first condensation takes place, the resulting development of heat causes the hydrogen, helium and light gases to be expelled. This may explain the existence of gaseous nebulae, which are often found intimately associated with star-clusters, a good example being the nebulosity surrounding the Pleiades. As the nuclei grow by the attraction of matter they begin to be capable of retaining the lighter gases, and atmospheres of hydrogen and helium are formed. The temperature of the photosphere at this stage has reached a maximum, and the star is now of the helium type. Then follows a gradual absorption of first the helium and then the hydrogen, the photosphere grows continually cooler, and the star passes successively through the stages exemplified by Sirius, Procyon, the Sun, Arcturus and Antares. Some authorities, however, consider the Antarian (Type III.) stars to be in a very early stage of development and to precede the helium stars in the order of evolution; in that case they are in the stage when the temperature is still rising. Type IV. (carbon) stars are placed last in the series by all authorities; they seem, however, to follow more directly the solar stars than the Antarian. If the latter are considered to be in an early state this presents no difficulty; but if both Antarian and carbon stars are held to be evolved from solar stars, we may consider them to be, not successive, but parallel stages of development, the chemical constitution of the star deciding whether it shall pass into the third or fourth type. The Wolf-Rayet stars must probably be assigned to the earliest period of evolution; they are perhaps semi-nebulous. In this connexion it may be noted that the spectrum of Nova Persei, after passing through a stage in which it resembled that of a planetary nebula, has now become of the Wolf-Rayet type.

Density of Stars.—Interesting light is thrown on the question of the physical state of the stars by some evidence which we possess as to their densities. The mean density of the sun is about $1\frac{1}{3}$ times that of water; but many of the stars, especially the brighter ones, have much lower densities and must be in a very diffused state. We have necessarily to turn to binary systems for our data. When the orbit and periodic time is known, and also the parallax, the masses of the stars can be found. (If only the relative orbit is known, the sum of the masses can be determined; but if absolute positions of one component have been observed, both masses can be determined separately.) But even when, as in most cases, the parallax is unknown or uncertain, the ratio of the brightness to the mass can be accurately found. Thus it is found that Procyon gives about three times as much light as the sun in proportion to its mass, Sirius about sixteen times, and ζ Orionis more than ten thousand times. In these cases evidently either the star has a greater intrinsic brilliancy per square mile of surface than the sun, or is less dense. Probably both causes contribute. The phenomena of long-period variables show that the surface brilliancy may vary very greatly, even in the same star. The Orion stars have the highest temperature of all and have admittedly the greatest surface-luminosity, but the extreme brilliancy of ζ Orionis in proportion to its mass must be mainly due to a small density. For the Algol variables it is possible to form even more direct calculations of the density, for from the duration of the eclipse an approximate estimate of the size of the star may be made. A. W. Roberts concluded in this way that the average density of the Algol variables and their eclipsing companions is about one-eighth that of the sun. For β Lyrae G. W. Myers found a density a little less than that of air; the density is certainly small, but J. H. Jeans has shown that for this type of star the argument is open to theoretical objection, so that Myers's result cannot be accepted.

There are many stars, however, of which the brightness is less than that of the sun in proportion to the mass. Thus the faint companion of Sirius is of nearly the same mass as the sun, but gives only $\frac{1}{1000}$ of its light. In this case the companion, being about half the mass of Sirius itself, has probably cooled more rapidly, and on that account emits much less light. T. Lewis, however, has shown that the fainter component of the binary system is often the more massive. It may be that these fainter components are still in the stage when the temperature is rising, and the luminosity is as yet comparatively small; but it is not impossible that the massive stars (owing to their greater gravitation) pass through the earlier stages of evolution more rapidly than the smaller stars.

Distances and Parallaxes of the Stars.—As the earth traverses annually its path around the sun, and passes from one part of its orbit to another the direction in which a fixed star is seen changes. In fact the relative positions are the same as if the earth remained fixed and the star described an orbit equal to that of the earth, but with the displacement always exactly reversed. The star thus appears to describe a small ellipse in the sky, and the nearer the star, the larger will this ellipse appear. The greatest displacement of the star from its mean position (the semi-axis major of the ellipse) is called its parallax. If π be the parallax, and R the radius of the earth's orbit, the distance of the star is $R/\sin\pi$. The determination of stellar parallaxes is a matter of great difficulty on account of the minuteness of the angle to be measured, for in no case does the parallax amount to 1″; moreover, there is always an added difficulty in determining an annual change of position, for seasonal instrumental changes are liable to give rise to a spurious effect which will also have an annual period. Very special precautions are required to eliminate instrumental error before we can compare observations, say, of a star on the meridian in winter at 6 p.m. with observations of the same star in summer on the meridian at 6 a.m. The first determination of a stellar parallax was made by F. W. Bessel in the years 1837–1840, using a heliometer. He chose for his purpose the binary star 61 Cygni, which was the star with the most rapid apparent motion then known and therefore likely to be fairly near us, although only of the sixth magnitude. He found for it a parallax of 0·35″ a value which agrees well with more modern determinations. T. Henderson at the Cape of Good Hope measured the parallax of α Centauri, but his resulting value 1″ was considerably too high. More accurate determinations have shown that this star, which is the third brightest star in the heavens, has a parallax of 0·75″, this indicates that its distance is 25,000,000,000,000 m. So far as is known α Centauri is our nearest neighbour.

Formerly attempts were made to determine parallaxes by measuring changes in the absolute right ascensions and declinations of the stars from observations with the meridian circle. The results were, however, always untrustworthy owing to annual and diurnal changes in the instrument. Nowadays the determination is more usually made by measuring the displacement of the star relatively to the stars surrounding it. Hitherto the heliometer has been most extensively used for this purpose, D. Gill, W. L. Elkin, B. E. A. Peter and others have made their important determinations with it. The photographic method, however, now appears to yield results of equal precision, and is likely to be used very largely in the future. The quantity determined by these methods is the relative parallax between the star measured and the stars with which it is compared. To obtain the true parallax, the mean parallax of the comparison stars must be added to this relative parallax. It is, however, fair to assume that the comparison stars will rarely have a parallax as great as 0·01″; for it must be remembered that it is quite the exception for a star taken at random to have an appreciable parallax; particularly if a star has an ordinarily small proper motion, it is likely to be very distant. Still exceptional cases will occur where a comparison star is even nearer than the principal star; it is one of the advantages of the photographic method that it involves the use of a considerable number of comparison stars, whereas in the heliometric method usually only two stars, chosen symmetrically one on each side of the principal star, are used.

In the table are collected the parallaxes and other data of all stars for which the most probable value of the parallax exceeds 0·20″. Although much work has been done recently in measuring parallaxes, the number of stars included in such a list has not been increased, but rather has been considerably diminished; many large parallaxes, which were formerly provisionally accepted, have been reduced on revision. It cannot be too strongly emphasized that many of these determinations are subject to a large probable error, or even altogether uncertain. For one or two of the more famous stars such as α Centauri the probable error is less than ±0·01″; but for others in the list it ranges up to ±0·05″. To convert parallaxes into distance we may remember that a parallax of 1″ denotes a distance of 18½ billion miles, or 206,000 times the distance of the sun from the earth. A parallax of 0·01″ denotes a distance a hundred times as great, and so on, the distance and parallax being inversely proportional. A unit of length, which is often used in measuring stellar distances, is the *light year* or distance that light travels in a year; it is rather less than six billion miles.

Stars with Large Parallax.

The stars selected to be examined for parallax are usually either the brightest stars or those with an especially large proper motion. Neither criterion is a guarantee that the star shall have a measurable parallax. Brightness is particularly deceptive; thus Canopus, the second brightest star in the heavens, has probably a parallax of less than 0·01″, and so also has Rigel. These two stars must have an intrinsic brilliancy enormously greater than that of the sun, for if the sun were removed to such a distance (parallax 0·01″), it would appear to be of about the tenth magnitude.

Although the parallaxes hitherto measured have added greatly to our general knowledge of stellar distances and absolute luminosities of stars, a collection of results derived by various observers choosing specially selected stars is not suitable for statistical discussion. For this reason a series of determinations of parallax of 163 stars on a uniform plan by F. L. Chase, M. F. Smith and W. L. Elkin (*Yale Transactions*, vol. ii., 1906) constitutes a very important addition to the available data. The stars chosen were those with centennial proper motions greater than 40″, observable at Yale, and not hitherto attacked. It is noteworthy that no parallaxes exceeding 0·20″ were found; the mean was about 0·05″. It is greatly to be desired that a general survey of the heavens, or of typical regions of the heavens, should be made with a view to determining all the stars which have an appreciable parallax. This is now made possible by photography. If three plates (or three sets of exposures on one plate) are taken at intervals of six months, when the stars in the region have their maximum parallactic displacements, the first and third plates serve to eliminate the proper motion of the star, and the detection of a parallax is easy. Some progress with this scheme has been made. But even such an attempt to systematically plumb the universe can only make us acquainted with the merest inside shell. We should learn perhaps the distribution and luminosities of the stars within a sphere of radius sixty light years (corresponding to a parallax of about 0·05″), but of the structure of the million-fold greater system of stars, lying beyond this limit, yet visible in our telescopes, we should learn nothing except by analogy. Fortunately the study of proper motions teaches us with some degree of certainty something of the general mean distances and distribution of these more distant stars, though it cannot tell us the distances of individual stars.

There is another method of determining stellar distances, which is applicable to a few double stars. By means of the spectroscope it is possible to determine the relative orbital velocity of the two components, and this when compared with the period fixes the absolute dimensions of the orbit; the apparent dimensions of the orbit being known from visual observations the distance can then be found. The method is of very limited application, for in general the orbital velocity of a visual binary is far too small to be found in this way; one of its first applications has been made to α Centauri, with the result that the parallax found in the ordinary way is completely confirmed.

Proper Motions of Stars.—The work of cataloguing the stars and determining their exact positions, which is being pursued on so large a scale, naturally leads to the determination of their proper motions. The problem is greatly complicated by the fact that the equator and equinox, to which the observed positions of the stars must be referred, are not stationary in space, and in fact the movements of these planes of reference can only be determined by a discussion of the observations of stars. Halley was the first to suspect from observation the proper motions of the stars. From comparisons between the observed places of Arcturus, Aldebaran and Sirius and the places assigned to them by Alexandrian astronomers, he was led to the opinion that all three are moving towards the south (*Phil. Trans.* 1718). Jacques Cassini also proved that Arcturus had even since the time of Tycho Brahe shifted five minutes in latitude; for η Boötis, which would have shared in the change, if it had been due to a motion of the ecliptic, had not moved appreciably. It was early realized that the proper motions of the stars were changes of position relative to the sun, and that, if the sun had any motion of its own as compared with the surrounding stars as a whole, this would be shown by a general tendency of the apparent motions of the stars to be directed away from the point to which the sun was moving.

To determine proper motions it is necessary to have observations separated by as long a period of time as possible. Old catalogues of precision are accordingly of great importance. By far the most valuable of these is Bradley's catalogue of 3240 stars observed at Greenwich about 1750–1763, which has been re-reduced according to modern methods by A. Auwers. These stars include most of the brighter ones visible in the latitude of Greenwich, ranging down to about the seventh magnitude. An early catalogue which includes large numbers of stars of magnitude as low as 8·5 is that of S. Groombridge, containing 4200 stars within 52° of the north pole observed between 1806 and 1816. This has been re-reduced by F. W. Dyson and W. G. Thackeray, and proper motions derived by comparison with modern Greenwich observations. A very extensive determination of proper motions from a comparison of all the principal catalogues has been made by Lewis Boss. The results are given in his *Preliminary General Catalogue* (1910), which comprises the motions of 6188 stars fairly uniformly distributed over the sky, including all the stars visible to the naked eye. Of rather a different nature are J. G. Porter's catalogue (*Publications of the Cincinnati Observatory*, No. 12) and J. F. Bossert's catalogue (*Paris Observations*, 1890), which consist of lists of stars of *large* proper motion determined from a variety of sources. Recently the proper motions of faint stars have been determined by comparing photographs of the same region of the sky, taken with an interval of a number of years. At present the available intervals are too small for this method to have met with marked success. Large proper motions can however be found in this way. Their detection is especially simple when the stereo-comparator is used; this instrument enables the two eyes to combine the images of each star on two plates into one image (as in the stereoscope); when the star has moved considerably in the interval between the taking of the two plates, it appears to stand out from the rest in relief and is at once noticed.

The star with the greatest proper motion yet known was found by J. C. Kapteyn on the plates of the Cape Photographic *Durchmusterung.* Its motion of 8·7″ per year would carry it over a portion of the sky equal to the diameter of the full moon in about two centuries. In the table is given a list of the stars now known to have an annual proper motion of more than 3″. The faintness of the majority of the stars appearing in this list is noteworthy.

Stars with Large Proper Motion.

The majority of the stars have far smaller proper motions than these. Only 24% of the stars of Auwers-Bradley have proper motions exceeding 10″ per century, and 51% exceeding 5″ per century. With catalogues containing fainter stars the proportion of large proper motions is somewhat smaller, thus the corresponding percentages for the Groombridge stars are 12 and 31 respectively.

When the parallax of a star is known, we are able to infer from its proper motion its actual linear speed in miles per hour, in so far as the motion is transverse to the line of sight. The velocity in the line of sight can be determined by spectroscopic observation, so that in a few cases the motion of the star is completely known. Several stars appear to have speeds exceeding 100 m. per second, but of these the only one reliably determined is Groombridge 1830, whose speed is found to be about 150 m. per second. Probably the velocity of Arcturus is also over 100 m. per second; there is, however, no real evidence for the velocity of 250 m. per second which has sometimes been credited to it. The above are velocities transverse to the line of sight. The greatest radial velocities that have yet been found are about 60 m. per second; several stars (Groombridge 1830 among them) have radial speeds of this amount. The stars of the Helium type of spectrum are remarkable for the smallness of their velocities; from spectroscopic observations of over 60 stars of this class, J. C. Kapteyn and E. B. Frost have deduced that the average speed is only 8 m. per second. According to W. W. Campbell the average velocity in space of a star is 21·2 m. per second.

The Solar Motion.

When the proper motions of a considerable number of stars are collected and examined, a general systematic tendency is noticed. The stars as a whole are found to be moving towards a point somewhere in or near the constellation Canis Major. The motions of individual stars, it is true, vary widely, but if the mean motion of a number of stars is considered this tendency is always to be found. Now it is necessary to bear in mind that all observed motions are *relative*; and, especially in dealing with stellar motions, it is arbitrary what shall be considered at rest, and used as a standard to which to refer their movements. Accordingly this mean motion of the stars relative to the sun has been more generally regarded from another point of view as a motion (in the opposite direction—towards the constellation Lyra) of the sun relatively to the stars. In what follows we shall speak of this relative motion as a motion of the sun or of the stars indifferently, for there is no real distinction between the two conceptions. One of the problems, which has engaged a large share of the attention of astronomers in the last century, has been the determination of the direction of this "solar motion."

The first attempt to determine the solar apex (as the point towards which the solar motion is directed is termed) was made in 1783 by Sir William Herschel. Although his data were the proper motions of only seven stars, he indicated a point near λ Herculis not very far from that found by modern researches. Again in 1805 from Maskelyne's catalogue of the proper motions of 36 stars (published in 1790), he found the position, R.A. 245° 52′ and Dec. 49° 38′ N. The systematic tendency of the proper motions is so marked that the motions of a very few stars are quite sufficient to fix roughly the position of the solar apex; but attempts to fix its position to within a few degrees have failed, notwithstanding the many thousands of determined proper motions now available. The difficulties of the determination are twofold. There is a close interdependence between the constant of procession and the solar motion; the two determinations must generally be made simultaneously, and both depend very considerably on the systematic corrections required by the catalogues compared. But further, if these practical difficulties could be considered overcome in the best determinations, there is a vagueness in the very definition of the solar motion. The motion of the sun relative to the stars depends on what stars are selected as representative. There is no a priori reason to expect the same result from the different classes of stars, such as the brighter or fainter, northern or southern, nearer or more distant, Solar type or Sirian stars. There is for example some evidence that the declination of the solar apex is really increased when the motion is referred to fainter stars. For these reasons a really close agreement between the results of different investigators is not to be expected.

Of the various modern determinations of the apex, we give first those which depend, wholly or mainly, on the Auwers-Bradley proper motions. Setting A for the right ascension, D for the declination of the apex, these are:—

L. Boss $A = 17^h\ 48^m$ $D = +42°{\cdot}8$
L. Struve $A = 18^h\ 20^m$ $D = +23°{\cdot}5$
S. Newcomb $A = 18^h\ 10^m$ $D = +31°{\cdot}3$
J. C. Kapteyn $A = 18^h\ 14^m$ $D = +29°{\cdot}5$.

The large differences between these results, derived from the same material, depend mainly on the different systematic corrections applied by each astronomer to the declinations of Bradley. From the data of his *Preliminary General Catalogue* (1910), L. Boss found $A = 18^h\ 2^m$, $D = +34°{\cdot}3$. Having regard to the special precautions taken to eliminate systematic error, and to the fact that the stars used were distributed nearly equally over both hemispheres, it is fair to conclude that this is the most accurate determination yet made. From the Groombridge proper motions Dyson and Thackeray found $A = 18^h\ 20^m$, $D = +37°$. Other determinations have been made by O. Stumpe (*Ast. Nach.* No. 3000) and J. G. Porter (*Ast. Journ.* xii. 91), using mainly stars of large proper motions derived from various sources; their results are of the same general character. Most of the above investigators, besides giving a general result, have determined the apex separately for bright and faint stars, for stars of greater or less proper motion, and in some cases for stars of Sirian and Solar spectra. Considerable divergences in the resulting position of the apex are found.

Speed of the Solar Motion.

It will be seen that the proper motion of any star may be regarded as made up of two components. The part of the star's apparent displacement, which is due to the solar motion, is generally called the *parallactic* motion; the rest of its motion (*i.e.* its motion relative to the mean of all the stars, is called its *peculiar* motion (*motus peculiaris*). Regarded as a linear velocity, the parallactic motion is the same for all stars, being exactly equal and opposite to the solar motion; but its amount, as measured by the corresponding angular displacement of the star, is inversely proportional to the distance of the star from the earth, and foreshortening causes it to vary as the sine of the angular distance from the apex. To arrive at some estimate of the speed of the solar motion, we may consider the motions of those stars whose parallaxes have been measured, and whose actual linear speed is accordingly known (disregarding motion in the line of sight). If a sufficient number of stars are considered, their peculiar motions will mutually cancel and the parallactic or solar motion can then be derived. But not much reliance can be placed on this kind of determination. A very weighty objection is that the stars whose parallaxes are determined are mainly those of large proper motion and therefore not fairly representative of the bulk of the stars; in fact their peculiar motions will not neutralize one another in the mean. A better method is to derive the speed from the radial motions observed with the spectroscope. In this way W. W. Campbell from the radial motions of 280 stars found the velocity to be 20 kilometres per second with a probable error of $1\frac{1}{2}$ km. per second (*Astrophysical Journal*, 1901, vol. xiii). This result depends on the northern stars only. By the addition of the data for southern stars, so as to obtain a distribution fairly symmetrical over the whole sphere, S. S. Hough and J. Halm deduced a velocity of 20·8 km. per second towards the apex $A = 18^h\ 5^m$, $D = +26°$. The speed is very nearly four radii of the earth's orbit per year; thus the annual parallactic motion is equal to four times the parallax, for a star lying in a direction 90° from the solar apex; for stars nearer the apex or antapex it is foreshortened. This result, while it does not afford any means of determining the parallaxes of individual stars, enables us to determine the mean parallax of a group of stars, if we may assume their peculiar motions practically to cancel one another.

In researches on the solar motion the assumption is almost always made that the motions of the stars relatively to one another —the *peculiar* motions—are at random. The correctness of this hypothesis has long been under suspicion, but it has generally been accepted as the best simple approximation to the actual distribution of the motions that could be made. Naturally exceptional regions must be recognized; for example, a connected system such as the Pleiades, whose stars have the same proper motion, must constitute an exception. There can occasionally be traced a certain community of motion over a much larger area. Thus R. A. Proctor found that between Aldebaran and the Pleiades most of the stars have a motion positive in right ascension and negative in declination, a phenomenon which he designated "star-drift." A more precise investigation by L. Boss has shown that there is in this region a "moving cluster" of globular form. The stars composing this all have equal and parallel motions; about 40 stars brighter than the seventh magnitude are known to belong to it. The group consisting of five stars of Ursa Major together with Sirius has already been alluded to; another very marked group of 16 stars in Perseus, all of the Helium type of spectrum, form a similar association. Spectroscopic evidence has indicated that most of the stars of Orion are associated, and share nearly the same motion (or rather, in this case, absence of motion).

The Two Star Streams.

But, whilst recognizing the existence of local drifts and systems, and admitting the possibility of relative motion between the nearer and more distant, or other classes of stars, it is only recently that astronomers have seriously doubted the correctness of the hypothesis of random distribution of stellar motions as at least a rough representation of the truth. The hypothesis was put to the test by J. C. Kapteyn, with the result that it appears to be not even approximately accordant with the facts. His researches indicate that, instead of being haphazard, the proper motions of the star show decided preference for two "favoured" directions, apparently implying that the stars surrounding us do not constitute a simple system but a dual one. The motion of the stars in the mean towards Canis Major is thus a *resultant* motion, which, when examined more minutely, is found to be due to the intermingling of two great streams of stars moving in very different directions. These two streams or drifts prevail in every part of the sky examined, and contain nearly equal numbers of stars; that is to say, in whatever part of the sky we look about half the stars are found to belong to one and half to the other of the two great drifts. This hypothesis of two star-drifts does not imply that all the stars move in one or other of two directions. The stars have on this theory random peculiar motions in addition to the motion of the drift to which they belong, just as on the older theory the stars have peculiar motions in addition to the solar or parallactic motion shared by all of them. But the two theories lead to a very different statistical distribution of the stellar motions. The older one—which may be called the "one-drift" hypothesis, since according to it the stars appear to form a single drift moving away from the solar apex—requires that the apparent directions of motion should be so distributed that fewest stars are moving directly towards the solar apex, and most stars along the great circle away from the solar apex, the number decreasing symmetrically, for directions inclined on either side of this great circle, according to a law which can be calculated. This is found not to agree with the facts at all. The deviation is unmistakable; in general the direction from the solar apex is not the one in which most stars are moving; and, what is even more striking, the directions, in which most and fewest stars respectively move, are not by any means opposite to one another. It seems difficult to account for the very remarkable and unsymmetrical distribution of the motions, unless we suppose that the stars form two more or less separate systems superposed; and it has been found possible by assuming two drifts with suitably assigned velocities to account very satisfactorily for the observed motions.

The phenomenon of two drifts was discovered by an examination of the Bradley proper motions (*Brit. Assoc. Rep.*, 1905, p. 257), and has subsequently been confirmed by a discussion of the Groombridge proper motions (*Mon. Not. R.A.S.*, 1906, 67, p. 34; 1910, 71, p. 4). By an examination of the stars of very large proper motion F. W. Dyson has traced the presence of the two drifts in all parts of the sky. They have been shown to prevail among fainter stars down to magnitude 9·5, by an examination of the Greenwich-Carrington proper motions; these, however, only cover a region within 9° of the north pole. Of the behaviour of stars fainter than magnitude 9·5 there is at present no direct evidence. About 10,000 stars altogether were dealt with in the above-mentioned investigations. The general results indicate that one of the drifts is moving (relatively to the sun) directly away from a point near α Ophiuchi (about R.A. 270°, Dec. +12°), and the other from a point in Lynx (R.A. 83°, Dec. +60°). These two points may be called the apices of the two drifts, for they are analogues of the solar apex on the one-drift theory; they are about 110° apart. The velocities of the drifts differ considerably, the one whose apex is in Ophiuchus having about $1\frac{1}{2}$ times the speed of the other. We may conveniently distinguish the two drifts as the *slow-moving* and *fast-moving* drifts respectively; but it should be remembered that, since these motions are measured relatively to the sun, this distinction is not physically significant. The stars appear to be nearly equally divided between the two drifts. The magnitudes of the stars are distributed in the same way in each drift. There is also clear evidence that the mean distances of both drifts from us are very approximately the same. Thus we are led to regard the two systems as completely intermingled, a fact which adds considerably to the difficulty of explaining the phenomena otherwise than as produced by two great systems—*universes* they have been called—which have come together, perhaps, by their mutual attraction, and are passing through one another. The chances of individual stars of the two systems colliding are infinitesimal. Until the hypothesis has been thoroughly tested by an examination of the line-of-sight velocities of stars from the same point of view, this physical interpretation must be received with some degree of caution; but there can be no doubt of the reality of the anomalies in the statistical distribution of proper motions of the stars, and of these it offers a simple and adequate explanation.

Having determined the motions of the two drifts, and knowing also that the stars are nearly equally divided between them, it is evidently possible to determine the mean motion of the drifts combined. This is of course that relative motion of the sun and stars which we have previously called the solar motion. The position of the solar apex calculated in this way agrees satisfactorily with that found by the usual methods. It is naturally fairly close to the apex of the faster drift, but is displaced from it in the direction of the apex of the other drift. In this connexion it may be noticed that, when the smaller and larger proper motions are discussed separately, the latter category will include an unduly great proportion of stars belonging to the fast-moving drift, and the resulting determination will lead to a solar apex too near the apex of that drift, *i.e.* with too low a declination. This appears to be the explanation of Stumpe's and Porter's results; they both divided their proper motions into groups according to their numerical amount, and found that the declination of the solar apex progressively increased as the size of the motions used diminished. Another anomalous determination of the apex, due to H. A. Kobold (*Astro. Nach.*, 3163, 3451, and 3491) is also explained when the two drifts are recognized. Kobold, using a peculiar and ingenious method, found for it a declination −3°, which disagrees very badly with all other determinations; but it is a peculiarity of Kobold's method that it gives the line of symmetry of motion, which joins the apex and antapex, without indicating which end is the apex. Now the position of this line, as found by Kobold, actually is a (properly weighted) mean between the corresponding lines of symmetry of the two drifts, but naturally it lies in the *acute* angle between them, whereas the line of the solar motion is also a weighted mean between the two lines of drift, but lies in the *obtuse* angle between them.

The Structure of the Universe.—We now arrive at the greatest of all the problems of sidereal astronomy, the structure and nature of the universe as a whole. It can by no means be taken for granted that the universe has anything that may properly be called a *structure*. If it is merely the aggregate of the stars, each star or small group of stars may be a practically independent unit, its birth and development taking place without any relation to the evolution of the whole. But it is becoming more and more generally recognized that the stars are not unrelated; they are parts of a greater system, and we have to deal with, not merely the history of a number of independent units, but with a far vaster conception, the evolution and development of an ordered universe.

Limits of the Universe.

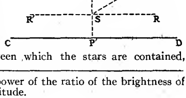
Our first inquiry is whether the universe extends indefinitely in all directions, or whether there are limits beyond which the stars are not distributed. It is not difficult to obtain at least a partial answer to this question; anything approaching a uniform distribution of the stars cannot extend indefinitely. It can be shown that, if the density of distribution of the stars through infinite space is nowhere less than a certain limit (which may be as small as we please), the total amount of light received from them (assuming that there is no absorption of light in space) would be infinitely great, so that the background of the sky would shine with a dazzling brilliancy. We therefore conclude that beyond a certain distance there is a thinning out in the distribution of the stars; the stars visible in our telescopes form a universe having a more or less defined boundary; and, if there are other systems of stars unknown to us in the space beyond, they are, as it were, isolated from the universe in which we are. It is necessary however to emphasize that the foregoing argument assumes that there is no appreciable absorption of light in interstellar space. Recently, however, the trend of astronomical opinion has been rather in favour of the belief that diffused matter may exist through space in sufficient quantity to cause appreciable absorption; so that the argument has no longer the weight formerly attached to it. Another line of reasoning indicates that the boundary of the universe is not immeasurably distant, and that the thinning out of the stars is quite perceptible with our telescopes. This depends on the law of progression in the number of stars as the brightness diminishes. If the stars were all of the same intrinsic brightness it is evident that the comparison of the number of stars of successive magnitudes would show directly where the decreased density of distribution began. Actually we know that the intrinsic brightness varies very greatly, so that each increase of telescopic power not only enables us to see stars more remote than before, but also reveals very many smaller stars within the limits previously penetrated. But notwithstanding the great variety of intrinsic brightness of the stars, the ratio of the number of stars of one magnitude to the number of the magnitude next lower (the "star-ratio") is a guide to the uniformity of their distribution. If the uniform distribution extends indefinitely, or as far as the telescope can penetrate, the star-ratio should have the theoretical value 3·98,[1] any decrease in density or limit to the distribution of the stars will be indicated by a continual falling off in the star-ratio for the higher magnitudes. H. H. Seeliger, who investigated this ratio for the stars of the *Bonn Durchmusterung* and *Southern Durchmusterung*, came to the conclusion (as summarized by Simon Newcomb) that for these stars the ratio ranges from 3·85 to 3·28, the former value being found for regions near the Milky Way and the latter for regions near the galactic poles. There is here evidence that even among stars of the *Durchmusterung* (9·5 magnitude), a limit of the universe has been reached, at least in the direction normal to the plane of the Milky Way. For the higher magnitudes J. C. Kapteyn has shown that the star-ratio diminishes still further.

The Galactic Plane.

In all investigations into the distribution of the stars in space one fact stands out pre-eminently, viz. the existence of a certain plane fundamental to the structure of the heavens. This is the *galactic plane*, well known from the fact that it is marked in the sky by the broad irregular belt of milky light called the Galaxy or Milky Way. But it is necessary to make a careful distinction between the galactic plane and the Galaxy itself; the latter, though it is necessarily one of the most remarkable features of the universe, is not the only peculiarity associated with the galactic plane. Its particular importance consists in the fact that the stars, bright as well as faint, crowd towards this plane. This apparent relation of the lucid stars to the Galaxy was first pointed out by Sir W. Herschel. For the stars visible to the naked eye a very thorough investigation by G. V. Schiaparelli has shown the relation in a striking manner. He indicated on planispheres the varying density of distribution of the stars over the sky. On these the belt of greatest density can be easily traced, and it follows very closely the course of the Milky Way; but, whereas the latter is a belt having rather sharply defined boundaries, the star-density decreases gradually and continuously from the galactic equator to the galactic poles. The same result for the great mass of fainter stars has been shown by Seeliger. The following table shows the density with which stars brighter than the ninth magnitude are distributed in each of nine zones into which Seeliger divided the heavens:—

Galactic latitude	N. Pole to 70° N.	70° N. to 50° N.	50° N. to 30° N.	30° N. to 10° N.	10° N. to 10° S.	10° S. to 30° S.	30° S. to 50° S.	50° S. to 70° S.	70° S. to S. Pole
Number of stars per square degree	2·78	3·03	3·54	5·32	8·17	6·07	3·71	3·21	3·14

The table, which is based on over 130,000 stars, shows that along the galactic circle the stars are scattered nearly three times more thickly than at the north and south poles of the Galaxy. What, however, is of particular importance is that the increase is gradual. No doubt many of the lucid stars which appear to lie in the Milky Way actually belong to it, and the presence of this unique cluster helps to swell the numbers along the galactic equator; but, for example, the increased density between latitudes 30° to 50° (both north and south) as compared with the density at the poles cannot be attributed to the Galaxy itself, for the Galaxy passes nowhere near these zones. The star-gauges of the Herschels exhibit a similar result; the Herschels counted the number of stars visible with their powerful telescopes in different regions of the sky, and thus formed comparative estimates of the density of the stars extending to a very high magnitude. According to their results the star-density increases continuously from 109 per square degree at the poles to 2019 along the galactic equator. In general, the fainter the stars included in the discussion the more marked is their crowding towards the galactic plane. Various considerations tend to show that this apparent crowding does not imply a really greater density or clustering of the stars in space, but is due to the fact that in these directions we look through a greater depth of stars before coming to the boundary of the stellar system. Sir William Herschel and afterwards F. G. W. Struve developed the view that the stars are contained in a comparatively thin stratum bounded by two parallel planes. The shape of the universe may thus be compared to that of a grindstone or lens, the sun being situated about midway between the two surfaces. Thus the figure represents a section of the (ideally simplified) universe cut perpendicular to the planes AB and CD between which the stars are contained,



[1] This number is the 3/2th power of the ratio of the brightness of stars differing by a unit magnitude.

S being the sun. Imagine this stratum to be uniformly filled with stars (of course in the actual universe instead of sharply defined boundaries AB and CD, we shall have a gradual thinning out of the stars) it follows that in the two directions SP and SP′ the fewest stars will be seen; these then are the directions of the galactic poles. As we consider a direction such as SQ farther and farther from the pole the boundary of the universe in that direction becomes more and more remote so that more stars are seen, and finally in the directions SR and SR′ in the galactic plane, the boundary is perhaps beyond the limits of our telescopes. That the universe must have a boundary in the directions SR and SR′, we can hardly doubt, but nothing is known of its shape or distance except that in all directions it must be far greater than SP or SP′; in particular it is not known whether the sun is near the centre or otherwise. That the sun is nearly midway between the two boundary planes can be tested by comparing the star-densities of the northern and southern galactic hemispheres. These are zone for zone very nearly equal; the slight excess of stars in the southern hemisphere perhaps implies that the sun is a little north of the central position. This is confirmed by the fact that the Milky Way is not quite a great circle of the celestial sphere, but has a mean south galactic latitude of about 1·7°.

If, instead of considering the whole mass of stars, attention is directed to those of large proper motion, which are therefore in the mean relatively near us, the crowding to the galactic plane is much less noticeable, if not indeed entirely absent. Thus Kapteyn found that the Bradley stars having proper motions greater than 5″ per century were evenly distributed over the sky. Dyson and Thackeray's tables show the same result for the Groombridge stars down to magnitude 6·5; but the fainter stars (with centennial proper motions greater than 5″) show a marked tendency to draw towards the galactic circle. The result is precisely what should be expected from the theory of the shape of the universe which has been set forth. If in the fig. we describe a sphere about S with radius SP so as just to touch the boundaries of the stratum of stars, then, provided a class of stars is considered wholly or mainly included within this sphere, no concentration of stars in the galactic plane is to be expected, for the shape of the universe does not enter into the question. It is only when some of the stars considered are more remote and lie outside this sphere (but of course between the two planes) that there is a galactic crowding. We infer that nearly all the stars down to magnitude 6·5, whose proper motions exceed 5″, are at a distance from the sun less than SP, whilst of the fainter stars with equally great proper motions a large proportion are at a distance greater than SP. This result enables us to form some sort of idea of the distance SP.

On considering the distribution of the stars according to their spectra, it appears that the Type II. (solar) stars show no tendency to congregate in the galactic plane. The result of course only applies to the brighter stars, for we have very little knowledge of the spectra of stars fainter than about magnitude 7·5. The explanation indicated in the last paragraph applies to this case also Type II. stars are in general much less intrinsically luminous than Type I., so that the stars known to be of this type must be comparatively near us, for otherwise they would appear too faint to have their spectra determined. They are accordingly within the sphere of radius SP (fig.), and consequently are equally numerous in every direction. The Type I. stars, being intrinsically brighter, are not so limited. According to F. McClean, of the stars brighter than magnitude 3·5, only the helium and not the hydrogen stars of Type I. show a condensation towards the galactic plane. Thus we see that the effect of limiting the magnitude to 3·5 is that the hydrogen stars are now practically all within the sphere SP, and it is only the helium stars, whose absolute luminosity is still greater, that are more widely distributed. Of the rarer types of spectra, stars of Type III. agree with those of Type II. in being evenly distributed over the sky; Types IV. and V. however, congregate towards the galactic plane. The most remarkable are the Type V. (Wolf-Rayet) stars; in their case the condensation into the galactic regions is complete, for of the 91 known stars of this type, 70 are actually in the Milky Way and the remaining 21 are in the Magellanic Clouds (two large clusters in the southern hemisphere, which resemble the Milky Way in several respects). Excluding the latter, the 70 Wolf-Rayet stars have a mean distance from the central galactic circle of only 2·6°. There can be little doubt that these stars belong to the Milky Way cluster, so that their presence is a property of the cluster rather than of the galactic plane in general. Spiral nebulae have the remarkable characteristic of avoiding the galactic plane, and it has been suggested that the space outside the limits of the *stellar* universe is filled with them. It does not, however, seem probable that their apparent anti-galactic tendency has such a significance; in the Magellanic Clouds spiral nebulae are very abundant, a fact which shows that there is no essential antipathy between the stars and the spiral nebulae.

As might be expected, the relative motion of the two great star-drifts is parallel to the galactic plane.

The Milky Way.

A glance at the Milky Way, with its sharply defined irregular boundaries, its clefts and diverging spur, is almost sufficient to assure us that it is a real cluster of stars, and does not merely indicate the directions in which the universe extends farthest. Barnard's photographs of its structure leave little doubt on the matter; the numerous rifts and dark openings show that its thickness cannot be very great. To complete our representation of the universe, it is therefore necessary to add to the fairly uniform distribution of stars between two planes a gigantic cluster of an annular or spiral form, also lying between the planes and completely surrounding the sun. The Milky Way is not of uniform brightness, so that we are perhaps nearer to some parts of it than to others, but it is everywhere very distant from the sun. Estimates of this distance vary, but it may probably be put at more than three thousand light years (parallax less than 0·001″). Nevertheless the Milky Way contains a fair proportion of lucid stars, for these are considerably more numerous in the bright patches of the Milky Way than in the rifts and dark spaces.

Distribution and Luminosity of the Stars.

It has been seen that the parallaxes afford little information as to the distribution of the main bulk of the stars and that the chief evidence on this point must be obtained indirectly from their proper motions. Our principal knowledge of this subject is due to Kapteyn (*Gröningen Publications*, Nos. 8 and 11), and though much of his work is provisional, and perhaps liable to considerable revision when more extensive data are obtainable, it probably gives an idea of the construction of the universe sufficiently accurate in all essential respects. As has been explained the mean distance of a group of stars can be readily determined from the parallactic motion, which, when not foreshortened, is approximately four times the parallax; but to obtain a complete knowledge of the distribution of stars it is necessary to know, not merely the mean parallax of the group, but also the frequency law, *i.e.* what proportion of stars have a quarter, half, twice or three times, &c., the mean parallax. One result of Kapteyn's investigations may be given here. Taking a sphere whose radius is 560 light years (a distance about equal to that of the average ninth magnitude star), it will contain:—

1 star	giving from	100,000	to	10,000	times	the light of the sun
26 stars	,,	10,000	,,	1,000	,,	,, ,,
1,300 ,,	,,	1,000	,,	100	,,	,, ,,
22,000 ,,	,,	100	,,	10	,,	,, ,,
140,000 ,,	,,	10	,,	1	,,	,, ,,
430,000 ,,	,,	1	,,	0·1	,,	,, ,,
650,000 ,,	,,	0·1	,,	0·01	,,	,, ,,

Whether there is an increasing number of still less luminous stars is a disputed question.

The comparative nearness of the stars of the solar type, which we have had occasion to allude to, is confirmed by the fact that their proper motions are on the average much larger than those of the Sirian stars. Kapteyn finds that magnitude for magnitude, the absolute brightness of the solar stars is only one-fifth of that of the Sirian stars, so that in the mean they must be at less than half the distance. As the numbers of known stars of the two types are nearly equal, it is clear that, at all events in our immediate neighbourhood, the solar stars must greatly outnumber the Sirian.

References.—Of modern semi-popular works entirely devoted to and covering the subjects treated of in this article the principal is Simon Newcomb's *The Stars, a Study of the Universe*; mention must also be made of Miss A. M. Clerke's *The System of the Stars* (2nd ed., 1905), which contains full references to original papers; *Problems in Astrophysics*, by the same author, may also be consulted. The following works of reference and catalogues deal with special branches of the subject; for variable stars, Chandler's "Third Catalogue," *Astronomical Journ.* (1896), vol. xvi., is now very incomplete; *Harvard Annals*, vol. lv., pt. 1, and vol. lx., No. 4, together constitute a catalogue of 3734 variable stars; ephemerides of over 800 variables are given in the *Vierteljahrsschrift* of the *Astronomische Gesellschaft*. For double stars see Burnham's *General Catalogue* (1907), and Lewis, *Memoirs of the R.A.S.*, vol. lvi.; the orbits of the principal binaries are discussed in T. J. J. See, *Evolution of Stellar Systems*, and another list will be found in *Lick Observatory Bulletin*, No. 84. A list of spectroscopic binaries discovered up to 1905 is given in *Lick Observatory Bulletin*, No. 79. For the spectrum analysis of stars, Scheiner's *Astronomical Spectroscopy* (trans. by Frost) may be consulted. The "Draper Catalogue," *Harvard Annals*, vol. xxvii., gives the classification according to spectrum of over 10,000 stars; for the brighter stars *Harvard Annals*, vol. l. forms a more complete catalogue. Of the numerous memoirs discussing stellar spectra in relation to evolution, A. Schuster, "The Evolution of Solar Stars," *Astrophysical Journ.* (1903), vol. xvii., may be mentioned as giving a concise survey of the subject. (A. S. E.)

STARAYA RUSSA, a town of Russia, in the government of Novgorod, 58 m. S. of the city of Novgorod, on the river Polista, by means of which and Lake Ilmen it is brought into steamer communication with St Petersburg. Pop., 15,234. Brine springs on the east of the town were used as a source for the supply of salt as late as 1865; at present they are used only as mineral waters (temperature 51–54° F.), having a great resemblance to those of Kreuznach in Germany. Some thousands of visitors resort to them every summer, and owing to this circumstance Staraya Russa is better built and better kept than any other town in the government of Novgorod. The inhabitants are supported chiefly by the summer visitors. There is a trade in rye, oats and flax shipped to St Petersburg. The name of Staraya Russa occurs in Russian annals as far back as 1167. It belonged to the republic of Novgorod, and suffered continually in the wars between Russia, Lithuania and Livonia. It was afterwards annexed to Moscow.

STARA ZAGORA (Turk. *Eski-Zagra*), the capital of a department of Bulgaria, in Eastern Rumelia, on the southern slope of the Karaja Dagh, 70 m. N.W. of Adrianople, with which it is connected by railway. Pop. (1906), 20,647. It is surrounded by vineyards, and has also cloth and carpet manufactures, copper foundries and tanneries. The production of silk and attar of roses is carried on in the district, which contains numerous mineral springs. The town having been almost wholly destroyed during the Russo-Turkish War of 1877–78, was rebuilt on a regular plan, with wide and broad streets radiating from a fine central square, where are situated the principal public buildings. During the rebuilding, important Thracian, Roman, Byzantine and Turkish antiquities were discovered.

Stara Zagora, founded probably by the Macedonians, was known to the Romans as Augusta Traiana, but afterwards, to distinguish it from a Macedonian town of this name, it was named Beroe or Berrhoea. By the Turks the name was changed in the 17th century to Eski-Zagra or Eski-Zaara, but after 1878 the Bulgarian name of Stara Zagora came into general use.

STARBOARD AND LARBOARD, nautical terms for the right and left sides respectively of a ship, looking towards the bows. The final part of these is Old English *bord*, board, the side of a ship, now used for a plank of wood. In starboard (O. Eng. *steorbord*) the first part certainly means "steer," and "steering side" therefore refers to the time when vessels were steered by a paddle or sweep worked from the right side. In Old English the left side of a ship was known as *baecbord*, back board, the side of the vessel to the back of the steersman. This is paralleled in all other Teutonic languages, cf. German *backbord*, and has been adopted in Romanic languages, cf. French *bâbord*. *Baecbord* did not survive in Middle English, in which its place was taken by *laddeborde* or *latheborde*. In the 16th century the word takes the forms *lerbord*, *leerebord* or *larbord*, probably by assimilation to *ster-*, *steere-*, and *star-bord*. There is much doubt as to the origin of the term and the curious change from *laddebord* to *larboard*. Skeat (*Etym. Dict.*) suggests that these may be two distinct words. The earlier form is usually connected with "lade," to put cargo on board a vessel, the left side being that on which this was usually done, for the ship when in port would lie with her left side against the quay wall, her head pointing to the entrance. If the later form is not due to mere assimilation to starboard, it may contain a word meaning empty (O. Eng. *gelär*, Ger. *leer*), and refer to that side of the vessel where the steersman does not stand. Owing to the similarity in sound between starboard and larboard, the word port is now used for the left side. The substitution of this for the older term was officially ordered in the British navy by an admiralty order of 1844, and in the United States of America by a navy department notice in 1896. The use of port in this sense is much older; it occurs in Manwaring's *Seaman's Dictionary* (1625–1644). In this usage port may either mean "harbour" (Lat. *portus*), the ship lying with its left side against the port or quay for unloading, or "opening," "entrance" (Lat. *porta*, gate), for the cargo to be taken on board; cf. "porthole."

STARCH, an organized product of the vegetable kingdom, forming one of the most important and characteristic elements of plant life. It originates within the living vegetable cell through the formative activity of chlorophyll under the influence of light, and is consequently an unfailing characteristic of all plants containing that body. Starch found within leaves and other green parts of plants is assimilated and transformed with great rapidity; accumulations of it are carried as starch-formers, and redeposited as starch in special reservoirs or portions of plants as the period of maturity approaches. In this way the body is found to gorge the stems of certain palms—the sago, &c.—just before these plants begin to form their fruit; it is the principal constituent of the underground organs of biennial and perennial plants, tap-roots, root-stocks, corms, bulbs and tubers; and it is abundantly stored in many fruits and seeds, as in the cereals and pulses, in bananas, bread-fruit, &c. It occurs in minute granules varying in diameter from ·002 to ·185 millimetres; and the granules from different sources have each a distinct microscopic character. Under the microscope these granules are seen to consist of a nucleus or hilum surrounded by layers arranged concentrically or excentrically, and the relations of hilum and layers are the most distinctive features of individual starches (see H. Galt, *Microscopy of the Starches*, 1900). Starch consists of a white or yellowish-white glistening powder. It is only slightly acted on by cold water, but under the influence of heat in water it swells up, forming according to the proportions of starch and water a clouded opalescent paste. The soluble portion is called granulose, and the insoluble starch-cellulose; from the aqueous solution alcohol precipitates soluble starch. Iodine acts on it in water, producing a brilliant blue coloration, this reaction forming a very delicate and characteristic test. The colour disappears on heating, but is recovered when the mixture is cold. Diastase and dilute boiling sulphuric acid convert starch into a form soluble in hot water, whence it passes into a series of easily soluble dextrins, and finally into the condition of the sugars, dextrose and maltose. Chemically, starch is a carbohydrate with the formula $(C_6H_{10}O_5)_n$, where n is four or more.

As an economic product starch in its separate condition is a most important alimentary substance, the chief pure food starches being arrowroot, sago, tapioca and cornflour. In its combined condition, in cereals, &c., starch is a useful nutritive element. In its other industrial relations starch is used: (1) directly, as a thickening material in calico printing, for the dressing and finishing of many textiles, for laundry purposes, adhesive paste, and powder; and (2) indirectly, for the preparation of dextrin and British gum and starch sugar. Indian corn, wheat and rice starch are principally employed for the direct applications; and for the dextrin and starch-sugar manufacture potato starch is almost exclusively selected.

In the preparation of starch the object of the manufacturer is to burst the vegetable cell walls, to liberate the starch granules, and to free them from the other cell contents with which they are associated. When, as in the case of the potato, the associated cell contents, &c., are readily separated by solution and levigation the manufacture is exceedingly simple. Potato starch is prepared principally by carefully washing the potatoes and in a kind of rasping machine reducing them to a fine pulp, which is deposited in water as raw starch. The impurities of this starch—cellulose, albuminoids, fragments of potato, &c.—are separated by washing it in fine sieves, through the meshes of which the pure starch alone passes. The sieves are variously formed, some revolving, others moving horizontally or in such manner as to keep the material in agitation. The starch is then received in tanks, in which it settles, and so separates from the soluble albuminoids and salts of the potatoes. (The waste pulp which passes over the sieve is pressed, dried quickly, and sold as a low-grade cattle food.) The settling of the starch is much retarded by the dissolved albuminoids, and to hasten the separation small quantities of alum or sulphuric acid are employed. Alum coagulates the albumen and to that extent contaminates the starch, while the acid acts on the starch itself and is difficult of neutralization. After the starch has settled, the brown-coloured supernatant liquor is drawn off and the starch again washed either in tanks or in a centrifugal machine. Finally it is dried by spreading it in layers over porous bricks (a process not required in the case of starch washed in a centrifugal machine) and by exposure to the air, after which it still retains a large proportion of water, but is in a condition for making dextrin or starch-sugar. For further drying it is ground to a rough powder, and dried thoroughly in a hot chamber, then reduced to a powder and sifted. Potato starch is also made by a "rotting" process, in which potatoes are reduced to a pulp by slicing and are then heaped up till fermentation takes place; 100 ℔ of potatoes yield 15–16 ℔ of dry starch.

In dealing with the starches of the cereals, there is greater difficulty, owing to the presence of gluten, which with water forms a tough elastic body difficult of solution and removal. The difficulty is experienced in greatest measure in dealing with wheat, which contains a large proportion of gluten. Wheat starch is separated in two different ways: (1) the fermentation method, which is the original process, and (2) by mechanical means without preliminary fermentation. In the fermentation process whole wheat or wheaten meal is softened and swollen by soaking in water. Wheat grains are, in this condition, ground, and the pulp, mixed to a thickish fluid with water, is placed in tanks, where it ferments, developing acids which dissolve the gummy constituents of the wheat, with part of the gluten, and render the whole less tenacious. After full fermentation, the period of which varies with the weather and the process employed, the starch is separated in a washing drum. It is subsequently washed with water, which dissolves out the gluten, the starch settling in two layers—one comparatively pure, the other mixed with gluten and some branny particles. These layers are separated, the second undergoing further washing to remove the gluten, &c., and the remaining operations are analogous to those employed in the preparation of potato-starch. By the mechanical process wheaten flour is kneaded into a stiff paste, which, after resting for an hour or two, is washed over a fine sieve so long as the water passing off continues milky, whereby the starch is liberated and the greater part of the gluten retained as a gluey elastic mass in the sieve. The starch is subsequently purified by fermentation, washing and treatment in centrifugal machines. The gluten thus preserved is a useful food for diabetic patients, and is made with flour into artificial macaroni and pastes, besides being valuable for other industrial purposes. The fermentation process gives about 59 ℔ of starch and 11 of bran from 100 ℔ of wheat, whilst the mechanical process gives about 55 ℔ of starch and 12 of gluten.

Maize (Indian corn) starch is obtained by analogous processes, but, the proportion of gluten in the grain being smaller and less tenacious in its nature, the operations, whether chemical or mechanical, present fewer difficulties. Under one method the separation of maize starch is facilitated by steeping, swelling and softening the grain in a weak solution of caustic soda, and favourable results are also obtained by a process in which the pulp from the crushing mill is treated with water acidulated with sulphurous acid.

In the preparation of rice-starch a weak solution of caustic soda is also employed for softening and swelling the grain. It is then washed with pure water, dried, ground and sifted, and again treated with alkaline water, by which the whole of the nitrogenous constituents are taken up in soluble form. An acid process for obtaining rice-starch is also employed, under which the grain, swollen and ground, is treated repeatedly with a solution of hydrochloric acid, which also dissolves away the non-starchy constituents of the grain. The yield is about 85 ℔ per 100 of rice. Laundry starches are principally made from rice and from pulse.

See O. Saare, *Die Fabrikation der Kartoffelstärke* (1897).

STAR CHAMBER, the name given in the 15th, 16th and 17th centuries to an English court of justice. The name is probably derived from the stars with which the roof of the chamber was painted; it was the *camera stellata*. But it has also been derived from a Hebrew word *shetar* or *sh'tar*, a bond, on the supposition that the chamber of meeting was the room in which the legal documents connected with the Jews were kept prior to their expulsion from England by Edward I.

The origin and early history of the court are somewhat obscure. The curia regis of the 12th century, combining judicial, deliberative and administrative functions, had thrown off several offshoots in the court of king's bench and other courts, but the Crown never parted with its supreme jurisdiction. When in the 13th century the king's council became a regular and permanent body, practically distinct from parliament, this supreme jurisdiction continued to be exercised by the king in council. As the ordinary courts of law became more important and more systematic, the indefinite character of the council's jurisdiction gave rise to frequent complaints, and efforts, for the most part fruitless, were made by the parliaments of the 14th century to check it. The equitable jurisdiction of the chancellor, which grew up during the reign of Edward III. like the courts of law under Henry II., was derived from this supreme judicial power, which was yet unexhausted.

It is in the reign of Edward III., after an act of 1341, that we first hear of the chancellor, treasurer, justices and other members of the king's council exercising jurisdiction in the old chamber, or *chambre de estoiles*, at Westminster. In Henry VI.'s reign one Danvers was acquitted of a certain charge by the council in the *camera stellata*. Hitherto such acts of parliament as had recognized this jurisdiction had done so only by way of limitation or prohibition, but in 1453, about the time when the distinction between the ordinary and the privy council first became apparent, an act was passed empowering the chancellor to enforce the attendance of all persons summoned by the privy seal before the king and his council in all cases not determinable by common law. At this time, then, the jurisdiction of the council was recognized as supplementary to that of the ordinary courts of law. But the anarchy of the Wars of the Roses and the decay of local justice, owing to the influence of the great barons and the turbulence of all classes, obliged parliament to entrust wider powers to the council. This was the object of the famous act of 1487, which was incorrectly quoted by the lawyers of the long parliament as creating the court of star chamber, which was in reality of earlier origin.

The act of 1487 (3 Hen. VII.) created a court composed of seven persons, the chancellor, the treasurer, the keeper of the privy seal, or any two of them, with a bishop, a temporal lord and the two chief justices, or in their absence two other justices. It was to deal with cases of "unlawful maintainance, giving of licences, signs and tokens, great riots, unlawful assemblies"; in short with all offences against the law which were too serious to be dealt with by the ordinary courts. The jurisdiction thus entrusted to this committee of the council was not supplementary, therefore, like that granted in 1453, but it superseded the ordinary courts of law in cases where these were too weak to act. The act simply supplied machinery for the exercise, under special circumstances, of that extraordinary penal jurisdiction which the council had never ceased to possess. By an act of 1529 an eighth member, the president of the council, was added to the star chamber, the jurisdiction of which was at the same time confirmed. At this time the court performed a very necessary and valuable work in punishing powerful offenders who could not be reached by the ordinary courts of law. It was found very useful by Cardinal Wolsey, and a little later Sir Thomas Smith says its object was "to bridle such stout noblemen or gentlemen who would offer wrong by force to any manner of men, and cannot be content to demand or defend the right by order of the law."

It is popularly supposed that the star chamber, after an existence of about fifty years, disappeared towards the end of the reign of Henry VIII., the powers obtained by the act of 1487 being not lost, but reverting to the council as a whole. This may have been so, but it is more probable that the star chamber continued to exist side by side with the council, and the two bodies were certainly separate during the latter part of Elizabeth's reign. The act of 1540, which gave the king's proclamation the force of law, enacted that offenders against them were to be punished by the usual officers of the council, together with some bishops and judges "in the star chamber or elsewhere." It is difficult, if not impossible, to draw a clear distinction between the duties of the privy council and the duties of the star chamber at this time, although before the abolition of the latter there was a distinction "as to their composition and as to the matters dealt with by the two courts." During the reign of Elizabeth Sir Thomas Smith remarks that juries misbehaving "were many times commanded to appear in the star chamber, or before the privy council for the matter." The uncertain composition of the court is well shown by Sir Edward Coke, who says that the star chamber is or may be compounded of three several councils: (1) the lords and others of the privy council; (2) the judges of either bench and the barons of the exchequer; (3) the lords of parliament, who are not, however, standing judges of the court. William Hudson (d. 1635), on the other hand, considers that all peers had the right of sitting in the court, but if so they had certainly given up the privilege in the 17th century.

The jurisdiction of the star chamber was as vague as its constitution. Hudson says it is impossible to define it without offending the supporters of the prerogative by a limitation of its powers, or the lawyers by attributing to it an excessive latitude. In practice its jurisdiction was almost unlimited.

It took notice of riots, murder, forgery, felony, perjury, fraud, libel and slander, duels and acts tending to treason, as well as of some civil matters, such as disputes about land between great men and corporations, disputes between English and foreign merchants, and testamentary cases; in fact, as Hudson says, " all offences may be here examined and punished if the king will." Its procedure was not according to the common law. It dispensed with the encumbrance of a jury; it could proceed on rumour alone; it could apply torture; it could inflict any penalty but death. It was thus admirably calculated to be the support of order against anarchy, or of despotism against individual and national liberty. During the Tudor period it appeared in the former light, under the Stuarts in the latter. Under the Tudors, as S. R. Gardiner says, it was "a tribunal constantly resorted to as a resource against the ignorance or prejudices of a country jury," and adds that "in such investigations it showed itself intelligent and impartial." Under James I. and Charles I. all this was changed; the star chamber became the great engine of the royal tyranny. Hateful and excessive punishments were inflicted on those brought before the court, notable among whom were Prynne, Bastwick and Burton, and the odium which it gathered around it was one of the causes which led to the popular discontent against Charles I. As it became more unpopular its jurisdiction was occasionally questioned. An example of this kind occurred in 1629, but the barons of the exchequer who heard the case declared that the star chamber was created many years before the statute of Henry VII. and that it was " one of the most high and honourable courts of justice." It was abolished by an act of parliament of July 1641. In 1661 a committee of the House of Lords reported " that it was fit for the good of the nation that there be a court of like nature to the star chamber "; but nothing further was done in the matter.

For the history of the star chamber see Sir Thomas Smith, *Commonwealth of England* (1633); Lord Bacon, *History of Henry VII.*, edited by J. R. Lumby (Cambridge, 1881); William Hudson, " Treatise of the Court of Star Chamber," in vol. ii. of *Collectanea Juridica*; H. Hallam, *Constitutional History of England* (1876); W. S. Holdsworth, *History of English Law* (fol. 1902); G. W. Prothero, *Statutes and Constitutional Documents 1559–1625* (1894); W. Busch, *England under the Tudors* (1895); S. R. Gardiner, *History of England 1603–1642* (1883–1884); D. J. Medley, *English Constitutional History* (1907); and A. V. Dicey, *The Privy Council*. The pleadings in the star chamber are in the Record Office, London; the decrees appear to have been lost.

STARFISH, a popular term under which are included a large number of sea-animals, belonging all to the great group of Echinoderms, but to three distinct divisions of that group: the Asterids, the Ophiurids and the Crinoids (see ECHINODERMA). The Asterids or starfish proper include the cross-fish, the sun-star (see ECHINODERMA, fig. 17), the cushion-star, the butthorn, and many without a popular name. The common cross-fish or five-finger, *Asterias rubens*, of British seas, may be taken as typical (figs. 1 and 2), and the description will apply also to the American species *A. forbesi* and *A. vulgaris*. The animal consists of a central body or disk, produced into five arms or rays. The upper surface is covered with a leathery skin, strengthened by a rafter-work of little bones or plates, made of crystalline carbonate of lime, many of them bearing prickles of the same substance and small pincer-like bodies—the pedicellariae (see SEA-URCHIN). In the middle of the body is a small anal opening, and near the angle between two rays is a furrowed plate pierced by many minute pores and called the madreporite. The under surface of the body has the mouth in the centre, and from it deep grooves radiate to the ends of the arms. At the bottom of each groove is a water-vessel, which gives off branches to the podia or sucking-feet on each side of it. A section across this groove is given in the article ECHINODERMA, fig. 12 B. The arrangement and working of this hydraulic system is essentially the same as in the sea-urchin, except for the presence of plates at the bottom of the groove beneath the radial water-vessel, and the absence of any plates covering the groove. At the end of each ray is, as in the urchin, a single tentacle surrounded by pigment and connected with a definite plate called " terminal." Thus the terminals of a starfish correspond to the oculars of a sea-urchin (see ECHINODERMA, fig. 3). The stomach is not a long coil, but a simple sac with branched blind tubes extending into each ray. A generative gland also passes down the side of each ray, and emits the milt or eggs when ripe through a pore near the body. Spawning takes place in spring or early summer. A starfish can crawl in any direction by means of its sucking-feet, whether the surface be hard or rough or polished, or the softest silt, whilst its supple body can squeeze through incredibly narrow crevices. The rate of progress is about six inches a minute.

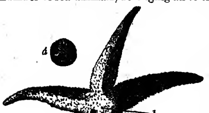


Fig. 1.—An Asterid, *Asterias rubens*, upper surface.

á, The same magnified.
b, Anus.
This starfish may be 9–12 in. across.

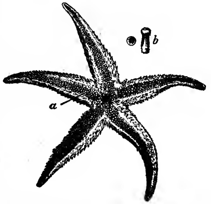

Fig. 2.—*Asterias rubens*, under surface.
a, The arm-groove with its row of sucking-feet or podia.
b, End of a podium, magnified.

The starfish are the scavengers of the sea, but unfortunately do not confine their attentions to decaying matter; they eat oysters, clams, mussels, barnacles, sea-snails, worms, crustacea and even smaller starfish. There is constant war between oyster-fishers and starfish; no less than 42,000 bushels of starfish were removed from the oyster-beds of Connecticut in a single year, but not till they had worked damage to the amount of $631,500. The simplest way in which a starfish eats is by taking small bits of food into the stomach, and ejecting the refuse again through the mouth. But since the mouth is quite small and the food often large, the starfish finds it more convenient to turn its stomach inside out and to wrap it around the animal to be eaten, which is then digested quietly and the stomach withdrawn again. In the case of oysters and similar bivalves, the starfish first has to open them; and this it does by fixing the suckers of one or two rays to one valve and those of the opposite rays to the other valve, while it may get a purchase by also holding on to some neighbouring object. It then begins to straighten out its rays. The oyster can withstand a very strong pull, but it cannot hold out against a long pull, and the starfish does not hurry. At last the oyster gives way, and the starfish has its reward; but its companions often join in, and you may see a whole ball of them interlaced round half-digested molluscs and rolling about. Starfish begin to eat voraciously when quite young; one less than ⅛th in. across has been observed to eat over fifty young clams of half that length in six days. The more a starfish has to eat the quicker it grows, and it may become sexually mature in less than a year, then producing many thousands of young. Fortunately the increase is kept in check by many causes. The young, while still in the stage of free-swimming larvae, are swallowed in millions by various fish. When they settle down on seaweed their bright colours attract eels and many small fishes. Later in life they are attacked by parasites, while those which stray into shallow water are eaten by gulls and crows. Freshets and cold currents are also destructive.

Probably the best way in which man can keep down the numbers of starfish is by dredging the seaweed in the latter half of July when it is covered with young; a single cartload thrown on shore would capture many millions. At a later stage tangles of hemp or cotton waste may be dragged over the oyster-beds, when the starfish will cling to them by their pedicellariae. They make excellent manure, but are of no further service to man. Fishermen who catch them in their nets or on their lines often tear them in half and throw them back into the sea. Some of these mutilated animals may, however, grow fresh rays, and thus one may find a starfish consisting of one large ray and four quite small ones, the whole shaped like a comet.

The Ophiurids (the name means "snake-tails") include the brittle-stars, sand-stars, and basket-fish or medusa-heads.

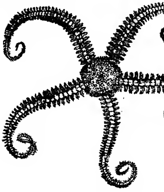

FIG. 3.—An Ophiurid, the Daisy Brittle-star (*Ophiopholis aculeata*); upper surface.

The two former, which may often be found hiding under the rocks, or in the seaweed, or in pools at low tide, resemble the ordinary starfish in having five distinct arms. These, however, as shown in fig. 3, are long and serpent-like, and are attached to a relatively small body or disk. The digestive and generative systems do not extend to the rays but are confined to the body. The arms are cylindrical and have no groove on the under side such as exists in starfish; but the water-vessel traverses the solid bones that form the axis of the arm, and the podia pass out through special openings (see ECHINODERMA, fig. 18).

In Ophiurids it is the arms that are used for locomotion and not the podia, so that the latter have no terminal suckers. The axial ossicles, which correspond to the plates flooring the arm-groove in a starfish, resemble vertebrae connected by pairs of straight muscular bundles, and articulated by tenon-and-mortise joints, according to whose degree of development the arms vary in their power of coiling. These vertebrae are encased in the tough outer skin of the arm, in which are developed plates. Spines borne by these plates aid the animal in locomotion. The skin of the disk also bears small plates, which are often covered with prickles. The mouth is on the under surface of the disk, and round it are a number of short, flat processes, the mouth-papillae, which serve as strainers. Inside the mouth are seen the five tooth-plates, borne on a strong frame of complicated structure. In the sand-stars the rays are comparatively short, with their spines closely pressed to their sides, so that they look like lizards' tails; in the brittle-stars the rays are much longer and more flexible, with the spines standing out, so that they look like wriggling centipedes attached round a little sea-urchin. The brittle-stars are more active than the sand-stars, and can go more than two yards in a minute; some of them, if seized, break off their arms, which continue breaking into smaller pieces; but the body can soon grow new ones. Sand-stars and brittle-stars are found in all seas, usually occurring in quantities, but are most abundant in the rock-pools of the tropics. By constantly sweeping their arms over the sea bottom, they gather food consisting of minute animals. They eat the bait of fishermen, and their fish as well if they find any already dead, but they are themselves a favourite food with many fish, notably the cod.

The basket-fish or medusa-heads are Ophiurids whose arms branch several times, their ends often curling and interlacing. They live in deeper water and are often brought up clinging to fishermen's lines.

The feather-stars (fig. 4) have a central body and five arms, each forking at least once and fringed with small branches (pinnules) which give the feathery appearance. The mouth is in the middle of the body, and from it grooves pass along the arms and all their branches. The animal lives with the mouth upwards, and although it can crawl and even swim by movement of its arms, it generally fixes itself to a stone or seaweed or some zoophyte, by means of a bunch of small jointed and hooked processes (cirri) growing from the back or under side of the body. It gets its food in this way: the arm-grooves (ECHINODERMA, fig. 12, C) are lined with minute hairs (cilia) always waving in the direction of the mouth, towards which they drive a stream of water; this stream, containing minute organisms, constantly flows through the coiled gut, which extracts nourishment from it. The feather-stars were formerly placed with the starfish, but they really belong to another class of Echinoderms—the Crinoidea.

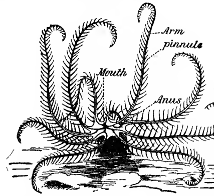

FIG. 4.—The Rosy Feather-star, *Antedon bifida*, attached by its cirri to a small stone, from which it is moving in the direction of the spectator by pushing with the branches of one arm and pulling with three branches of two arms. (Natural size.)

In 1823 J. V. Thompson, of Cork, discovered that the feather-star when quite young was fixed by a stalk, just as are nearly all crinoids (see ECHINODERMA, figs. 1 and 2). The stalked crinoids are not so numerous as they once were, but feather-stars belonging to about half a dozen genera (*Antedon*, *Actinometra*, &c.) are found in all seas at all depths, often in enormous numbers. (F. A. B.)

STARGARD, a town of Germany, in the Prussian province of Pomerania, situated on the left bank of the navigable Ihna, 20 m. E. of Stettin on the railway to Danzig and at the junction of lines to Posen, Schneidemühl and Cüstrin. Pop. (1905), 26,908. Formerly a member of the Hanseatic League, the town retains memorials of its early importance in the large church of St Mary, built in the 14th century, the 16th-century town-hall, and some gateways and towers dating from the 14th century. The walls which formerly surrounded it have been mostly converted into promenades. Extensive new law-courts and three large barracks are among the modern buildings. Stargard has a considerable market for cattle and horses, and carries on trade in grain, spirits and raw produce. Its manufactures include cigars, tobacco, wadding and stockings; and there are also iron-foundries, and linen and woollen factories in the town.

Stargard, mentioned as having been destroyed by the Poles in 1120, received civic rights in 1229, and became the capital of eastern Pomerania. As a Hanseatic town it enjoyed considerable commercial prosperity, but it had also to undergo siege and capture in the middle ages and during the Thirty Years' War. In 1807 it was taken by Schill. The name Stargard (from the Slavonic Starogad or Starigrod, meaning "old town") is common to several other towns in the north of Germany, of which the chief are Preussisch-Stargard, near Danzig, and Stargard an der Linde in Mecklenburg-Strelitz.

See Zuck, *Führer durch Stargard* (Stargard, 1900).

STARK, JAMES (1794–1859), British painter, was born in Norwich, and as he showed strong artistic inclinations early in life was, at the age of seventeen, articled to John Crome for three years. He was elected in 1812 a member of the Norwich Society, to the exhibitions of which he had already contributed; but in 1817 he migrated to London and entered the Royal Academy Schools. He soon returned to Norwich and did not finally settle in the metropolis until 1830, though he was meanwhile a regular contributor to the British Institution and Suffolk Street Galleries. In 1840 he moved to Windsor, but after an interval of some years went back to London, where he died in 1859. Between 1831 and 1859 most of his pictures were shown at the Royal Academy, though he still continued to exhibit occasionally in other galleries. He undertook in 1827 the publication of a work on *The Scenery of the Rivers of Norfolk*, which was completed seven years later; the illustrations he prepared for it have much topographical and artistic interest and show well the better qualities of his work. In his pictures the influence of Crome is plainly perceptible, and there is evidence also of his study of the Dutch landscape-painters; but he had little of Crome's largeness and power and his works charm rather by their gentle truth and quietness of manner than by their robustness of view or by their decisiveness of execution. There is one picture by him, "The Valley of the Yare," in the National Gallery of British Art.

STARK, JOHN (1728–1822), American soldier, was born at Nutfield, now Londonderry, New Hampshire, on the 28th of August 1728. In 1752 he was taken prisoner by the Indians but was ransomed by Massachusetts. During the Seven Years' War he served under Robert Rogers, first as a lieutenant and later as a captain, taking part in the battle of Lake George in 1755, the disastrous attack upon Ticonderoga in 1758, and the Ticonderoga-Crown Point campaign in 1759. At the beginning of the War of Independence he raised a regiment and as colonel did good service in the Battle of Bunker Hill, in the Canadian expedition, and in Washington's New Jersey campaign in the winter of 1776–77. In March 1777 he resigned his commission because other officers had been promoted over him. Later in the year, however, he was placed in command (by New Hampshire), with the rank of brigadier-general of militia, of a force of militiamen, with whom, on the 16th of August, near Bennington (*q.v.*), Vermont, he defeated two detachments of Burgoyne's army under Colonel Friedrich Baum and Colonel Breyman. For this victory, which did much to bring about the capitulation of General Burgoyne, Stark received the thanks of Congress and a commission as brigadier-general in the Continental Army (Oct. 4, 1777). He took part in the operations about Saratoga, and for a short time in 1778 and again in 1781 he was commander of the northern department. In September 1783 he was breveted major-general. He died at Manchester, New Hampshire, on the 8th of May 1822. John Stark's brother, William (1724–1776), served in the Seven Years' War and afterwards on the frontier; and at the outbreak of the War of Independence, piqued because he was not put in command of a regiment, he entered the British service.

See *Memoir and Official Correspondence of General John Stark* (Concord, N.H., 1860) by his grandson Caleb Stark (1804–1864), who wrote in 1831 *Reminiscences of the French War containing Rogers's Expeditions with the New England Rangers and an Account . . . of John Stark.*

STARLEY, JAMES (1830–1881), British inventor, the son of a farmer, was baptized at Albourne, Sussex, on the 13th of June 1830. At eighteen he ran away from home and started on foot for London, but on the way obtained work as a gardener at Lewisham, Kent, where he lived for a number of years. He had always been an ingenious mechanic, inventing trifling novelties and repairing watches and clocks in the neighbourhood, and when sewing machines began to be much used they attracted his practical attention, and aroused his inventive genius. Leaving his garden he went up to London and became working mechanic for a firm of sewing-machine makers. Here he was in his element, and in several particulars improved his principal's machines, and invented a new one with an arm attachment that permitted circular as well as straightforward work. With a fellow workman he moved in 1857 to Coventry, and started the manufacture of the "European" and other sewing machines from his patents. This was the beginning of the Coventry Machinists' Company, the pioneer of all the great bicycle and tricycle works which afterwards made that city the centre of the industry. Former acquaintances of Starley at Lewisham and elsewhere migrated to Coventry to become skilled mechanics for this company. In 1868 they began the manufacture, after a Paris model and at first for French use, of bicycles, several of the earliest suggested improvements being Starley's. A number of firms were soon devoting themselves exclusively to the manufacture of bicycles, and for one of these Starley—whose financial successes were always for others—designed the Coventry tricycle. As it was harder to propel than the bicycle he invented the balance gear, and applied it in the Salvo, which is the type of the present tricycle (*q.v.*). Starley died on the 17th of June 1881, and a public monument has been erected to his memory in Coventry. His nephew, J. K. Starley, patented the tangent wheel in 1874.

STARLING (O. Eng. *staer stearn*, and *sterlyng*; Lat. *sturnus*; Fr. *étourneau*), a well-known bird about the size of a thrush; though at a distance it appears to be black, when near at hand its plumage is seen to be brightly shot with purple, green and steel-blue, most of the feathers when freshly grown being tipped with buff. These markings wear off in the course of the winter, and in the breeding season the bird is almost spotless. It is the *Sturnus vulgaris* of ornithologists.

A full description of the habits of the starling[1] is unnecessary in this place. A more engaging bird scarcely exists, for its familiarity during some months of the year gives opportunities for observing its ways that few others afford, while its varied song, its sprightly gestures, its glossy plumage, and, above all, its character as an insecticide—which last makes it the friend of the agriculturist and the grazier—render it an almost universal favourite. The worst that can be said of it is that it occasionally pilfers fruit, and, as it flocks to roost in autumn and winter among reed-beds, does considerable damage by breaking down the stems.[2] The congregations of starlings are indeed very marvellous, and no less than the aerial evolutions of the flocks, chiefly before settling for the night, have attracted attention from early times, being mentioned by Pliny (*Hist. naturalis*, x. 24) in the 1st century. The extraordinary precision with which the crowd, often numbering several hundreds, not to say thousands, of birds, wheels, closes, opens out, rises and descends, as if the whole body were a single living thing—all these movements being executed without a note or cry being uttered—must be seen to be appreciated, and may be seen repeatedly with pleasure. For a resident the starling is rather a late breeder. The nest is commonly placed in the hole of a tree or of a building, and its preparation is the work of some little time. The eggs, from 4 to 7 in number, are of a very pale blue, often tinged with green. As the young grow they become very noisy, and their parents, in their assiduous attendance, hardly less so, thus occasionally making themselves disagreeable in a quiet neighbourhood. The starling has a wide range over Europe and Asia, reaching India; but examples from Kashmir, Persia and Armenia have been considered worthy of specific distinction, and the resident starling of the countries bordering the Mediterranean is generally regarded as a good species, and called *S. unicolor* from its unspotted plumage.

Of the many forms allied to the genus *Sturnus*, some of which have perhaps been needlessly separated therefrom, those known as Grackles (*q.v.*), are separately dealt with, and here we shall only notice one other, *Pastor*, containing a beautiful species *P. roseus*, the Rose-coloured Starling, which is not an unfrequent visitor to the British Islands. It is a bird of most irregular and erratic habits—a vast horde suddenly arriving at some place to which it may have hitherto been a stranger, and at once making a settlement there, leaving it wholly deserted as soon as the young are reared. This happened in the summer of 1875 at Villafranca, in the province of Verona, the castle of which was occupied in a single day by some 12,000 or 14,000 birds of this species, as has been graphically told by Sig. de Betta (*Atti del r. isl. veneto*, 5th series, vol. ii.);[3] but similar instances have been before recorded—as in Bulgaria in 1867, near Smyrna in 1856, and near Odessa in 1844, to mention only some of which particulars have been published.[4]

[1] They are dwelt on at some length in Yarrell's *British Birds*, ed. 4, vol. ii. pp. 229–241.

[2] A most ridiculous and unfounded charge has been, however, more than once brought against it—that of destroying the eggs of skylarks. There is little real evidence of its sucking eggs, and much of its not doing so; while, to render the allegation still more absurd, it has been brought by a class of farmers who generally complain that skylarks themselves are highly injurious.

[3] A partial translation of this paper is given in the *Zoologist* for 1878, pp. 18–22.

[4] It is remarkable that on almost all of these occasions the locality pitched upon has been, either at the time or soon after, ravaged

STARNBERG, a village and climatic health resort of Germany, in the kingdom of Bavaria, on the Starnberger See, 16 m. by rail S. from Munich. Pop. (1905), 3257. It has an evangelical and a Roman Catholic church, an old castle (now government offices) and a bathing establishment. The Starnberger See (or Würmsee) is a lake with a length of 12 m., a breadth of 3 m., and covering 23 sq. m. Its greatest depth is about 400 ft. The lake is girdled by hills, studded with attractive villa residences, commanding beautiful and extensive views of the Alps. On the Roseninsel, an island in the lake, remains of lacustrine dwellings have been discovered. The waters abound in fish. In the summer steamboats ply, touching at all the villages lying on the shores.

See Ule, *Der Würmsee in Oberbayern* (Leipzig, 1901).

STAR-NOSED MOLE (*Condylura cristata*), a North American species, the single representative of its genus. In burrowing habits it resembles the European mole, but is distinguished from all other members of the family *Talpidae* by the presence of a ring of tentacles round the nostrils, probably serving as organs of touch.

STARODUB, a town of Russia, in the government of Chernigov, 98 m. N.E. of the city of Chernigov. It is regularly built, with broad straight streets, and the houses are surrounded by large gardens. Pop. 12,451; Little Russians with about 5000 Jews. Tanning and the manufacture of copper wares are carried on, and there is a trade in corn and hemp exported to Riga and St Petersburg. As early as the 11th and 12th centuries Starodub was a bone of contention between different Russian princes, who appreciated its strategic position. The Mongols seem to have destroyed it in the middle of the 13th century, and its name does not reappear until the following century. During the 15th and 16th centuries the Russians and Lithuanians were continually disputing the possession of its fortress, and at the beginning of the 17th century it became a stronghold of Poland.

STARVATION, the state of being deprived of the essentials of nutrition, particularly of food, the suffering of the extremities of hunger and also of cold (see HUNGER AND THIRST). The word is an invented hybrid, attributed, according to the accepted story, to Henry Dundas, 1st Viscount Melville, who used it in a parliamentary debate on American matters in 1775 and gained thereby the nickname of "Starvation Dundas" (see H. Walpole's *Letters*, ed. Cunningham, viii. 30; and *Notes and Queries* no. 225). The English word "to starve" meant originally "to die," as in O. Eng. *steorfan*, Du. *sterven*, Ger. *sterben*, but was particularly applied to death from hunger or cold.

STAS, JEAN SERVAIS (1813–1891), Belgian chemist, was born at Louvain on the 21st of August 1813. He studied for a medical career and took his doctor's degree, but soon turned to chemistry. In 1835 after much trouble he gained admission to J. B. A. Dumas's laboratory in Paris in order to continue a research on phloridzin which he had begun in an attic in his father's house, and he was associated with that chemist in several researches, including his redetermination of the atomic weight of carbon. In 1840 he left Paris on his appointment to the chair of chemistry at the École Royale Militaire in Brussels. There he remained for more than a quarter of a century, but before he had served the thirty years necessary to secure a pension he was obliged to resign through a malady which affected his speech. He was then appointed to a post in connexion with the Mint, but gave it up in 1872, and spent the rest of his life in retirement in Brussels, where he died on the 13th of December 1891. Stas's name is best known for his determination of the atomic weights of a number of the more important elements. His work in this field was marked by extreme care, and he adopted the most minute precautions to avoid error, with such success that the greatest variation between his numerous individual determinations for each element was represented by from 0·005 to 0·01. Though he started with a predilection in favour of Prout's hypothesis he was later led by the results he obtained and by his failure to find any evidence of dissociation in the elements to regard it as a pure illusion and to look upon the unity of matter as merely an attractive speculation unsupported by proof. Nevertheless, a few years before his death, à propos of the close approximation to integers presented by a number of the atomic weights of the elements when hydrogen is taken as unity, he remarked, "Il faut croire qu'il y a quelque chose là-dessous." In connexion with the poisoning of Count Hippolyte de Bocarmé with nicotine in 1850 Stas worked out a method for the detection of the vegetable alkaloids, which, modified by Friedrich Julius Otto (1809–1870), professor of chemistry at Brunswick, has been widely used by toxicologists as the Stas-Otto process.

STASINUS, of Cyprus, according to some ancient authorities the author of the *Cypria* (in 11 books), one of the poems belonging to the epic cycle. Others ascribed it to Hegesias (or Hegesinus) of Salamis or even to Homer himself, who was said to have written it on the occasion of his daughter's marriage to Stasinus. The *Cypria*, presupposing an acquaintance with the events of the Homeric poem, confined itself to what preceded, and thus formed a kind of introduction to the *Iliad*. It contained an account of the judgment of Paris, the rape of Helen, the abandonment of Philoctetes on the island of Lemnos, the landing of the Achaeans on the coast of Asia, and the first engagement before Troy. It is probable that the list of the Trojans and their allies (*Iliad*, ii. 816–876), which formed an appendix to the catalogue of the Greek ships, is abridged from that in the *Cypria*, which was known to contain a list of the Trojan allies. Proclus, in his *Chrestomathia*, gave an outline of the poem (preserved in Photius, *cod.* 239).

See F. G. Welcker, *Der epische Cyclus* (1862); D. B. Monro, Appendix to his edition of *Odyssey*, xiii.–xxiv. (1901); T. W. Allen, "The Epic Cycle," in *Classical Quarterly* (Jan. 1908, sqq.); and CYCLE.

STASSFURT, a town of Germany, in the Prussian province of Saxony, and one of the chief seats of the German salt-producing industry, situated on both sides of the Bode, 20 m. S.W. of Magdeburg by the railway to Aschersleben. Pop. (1905), 18,310. It is still surrounded in part by the ruins of its ancient walls, but, with the exception of the parish church of St John (15th century), there are no buildings worthy of special notice. Although saline springs are mentioned here as early as the 13th century, the first attempt to bore for salt was not made until 1839, while the systematic exploitation of the salt-beds, to which the town is indebted for its prosperity, dates only from 1856. The shafts reached deposits of salt at a depth of 850 ft., but the finer and purer layers lie more than 1100 ft. below the surface. Besides the rock-salt, which is excavated by blasting, the saline deposits of Stassfurt yield a considerable quantity of deliquescent salts and other saline products, which have encouraged the foundation of numerous chemical factories in the town and in the neighbouring village of Leopoldshall, which lies in Anhalt territory. The rock-salt works are mainly government property, while the chemical factories are in private hands.

See Precht, *Salzindustrie von Stassfurt und Umgebung* (Stassfurt, 1891); and Westphal, *Geschichte des königlichen Salzwerks zu Stassfurt* (Berlin, 1901).

STATE. As currently employed in that department of political science which concerns itself, not with the relations of separate political entities, but with the political composition of society as a whole, the word state expresses the abstract idea of government in general, or the governing authority as opposed to the governed, and is thus used by Herbert Spencer in all his discussions of government and society. Louis XIV.'s "l'état, c'est moi," Rousseau's theory of the "contrat social," Bastiat's "donne à l'état le strict nécessaire et garde le reste pour toi," all imply this opposition. Hobbes regards the state, or, as he calls it, the commonwealth, as "one person for whose acts a great multitude by

Definition.

by locusts, which the birds greedily devour. Another fact worthy of attention is that they are often observed to affect trees or shrubs bearing rose-coloured flowers, as *Nerium oleander* and *Robinia viscosa*, among the blossoms of which they themselves may easily escape notice, for their plumage is rose-pink and black shot with blue.

mutual covenants, one with another, have made themselves every one the author, to the end he may use the means and strength of them all as he shall think expedient for their peace and common defence."

The term is also used to distinguish the civil from the ecclesiastical authority in countries where they are or have been in conflict.

A large number of definitions and classifications, according to political structure, international status, national homogeneity, &c., have been attempted, but it is beyond the scope of a short article to do more than mention these different senses of a word so variously employed.

Attributes in International Law.

In international law the term has a more precise meaning, according to which the state is the external personality or outward agency of an independent community. In its fullest form its attributes are: (*a*) possession of sovereign power to pledge the community in its relations with other similarly sovereign communities, (*b*) independence of all external control, and (*c*) dominion over a determinate territory. In practice, however, there are still incomplete forms of states which join in the international life of states, paramount states whose relations to subordinate parts of their empire are in a condition of uncertainty, and there is, at any rate, one body carrying on international state intercourse without dominion over any territory at all. Thus, Great Britain, has diplomatic relations, purely formal though they may be, with several of the subordinate states forming the German Empire. Egypt, while legally under the suzerainty of the Porte, is practically a British protectorate. Great Britain treats Cyprus as a dependency, though she is in mere occupation of the island for the purpose of carrying out certain reforms for the protection of Christians. Austria-Hungary considered herself in the same position, though she occupied Bosnia and Herzegovina "without affecting the rights of sovereignty of his majesty the Sultan on those provinces." Though Bulgaria, by the Treaty of Berlin, was an "autonomous and tributary principality under the suzerainty of his imperial majesty the Sultan," Turkey did not consider her suzerainty to involve her in the war of 1885 between her vassal and Servia. The Roman Catholic Church has permanent diplomatic relations as an independent state, though it has no independent territory against which international rights can be enforced. We saw in the Boer War the army of an annexed community wandering from place to place recognized as a belligerent with whom Great Britain negotiated as an independent state.

A new and somewhat shadowy form of suzerainty is growing up in the "paramountcy" first enunciated (with the concurrence of Great Britain) by the President of the United States in 1823 (see MONROE DOCTRINE), asserted with a certain measure of success against Great Britain in 1896 (see VENEZUELA, also ARBITRATION), and proclaimed formally by the United States at the Hague peace conference in 1899 as a condition of her signature of the Peace Convention. While the Spanish republics of Central and South America are recognized in international law as sovereign states, they can only be said to fulfil the conditions of absolute independence subject to the limitations which the Monroe Doctrine has placed upon their treaty-making powers with Europe.[1]

British and Continental Conceptions.

"In constitutional law, the state," says a leading English authority, "is the power by which rights are created and maintained, by which the acts and forbearances necessary for their maintenance are habitually enforced" (Anson, *Law and Custom of the Constitution*, pt. i. p. 2). In France, where the state embraces a hierarchy of bodies and authorities culminating in the president of the republic, whose acts are the final form of a series of incomplete acts of the members of the hierarchy, it comes nearer to the theoretical meaning of the word. In Great Britain the sovereign power of the state is diffused among a number of authorities which have rights against each other and stand in independent relation towards the individual citizens. Actions can be brought by private citizens in the ordinary law courts against individual authorities, and there is no system of hierarchical responsibility which prevents a state official from being personally accountable for his administrative conduct. In A. V. Dicey's admirable *Introduction to the Study of the Law of the Constitution*, this distinction between the French, or, as we should rather call it, continental system of entire subordination of the organs to the state as a whole, and the less logical British system is dwelt upon. "Few things," he observes, "are more instructive than the examination of the actions which have been brought in Great Britain against officers for retaining ships about to proceed to sea. Under the Merchant Shipping Act 1876 the board are open to detain any ship which, from its unsafe and unseaworthy condition, is a serious danger to human life." "Most persons would suppose that the officials of the board of trade, so long as they—bona fide and without malice or corrupt motive—endeavour to carry out the provisions of the statute, would be safe from action at the hands of a shipowner. This, however, is not so. The board and its officers have more than once been sued with success. They have never been accused of either malice or negligence, but the mere fact that the board acts in an administrative capacity is not a protection to the board; nor is mere obedience to the orders of the board an answer to an action against its servants" (p. 324).

In England, we may say, the notion of state, from the constitutional point of view, is still inchoate, but the play of international intercourse seems to be gradually leading to a clearer conception of the fact that an increasing national responsibility requires a corresponding increase in the power of co-ordinate state control. An instance of its absence is shown by the loose way in which the British Crown has granted governing powers to chartered companies (see RAID). This uncertainty applies as much to the United States as to Great Britain. In the Louisiana lynching riots, of which some Italian citizens were the victims, it was contended that the United States government was not responsible, and that the responsibility fell upon the government of Louisiana alone. This contention could not be pressed, and compensation was of course paid to Italy. Similar difficulties arose in connexion with the Japanese school question in California. The subject is well known to have raised apprehension as to the adequacy of the United States system to meet its centralized state responsibilities.

Another, and, in some respects, more dangerous feature of an inchoate conception of state responsibility is the growing apart, so to speak, of certain British dependencies. The British state, for international purposes, is the British Empire, for domestic purposes it is the United Kingdom. Any limb of the former's huge body can have interests different from those of the United Kingdom, and involve its responsibility. A significant step towards concentration of liability and control was taken by the Australian colonies in the federation brought about by the Commonwealth Act of 1900. Under this act, by the way, an element of confusion has been created by the application of the term "state" to the federating colonies. Section 6 of the act provides "the states" shall mean such of the colonies of New

[1] Great Britain, in acceding to the arbitration imposed by President Cleveland, has, in the opinion of a number of American and Continental publicists, recognized the Monroe Doctrine. See Chrétien, *Principes*; De Beaumarchais, *La Doctrine de Monroe*; De Bustamente, *Le Canal de Panama et le droit international*; De Pressensé, "La Doctrine de Monroe et le conflit anglo-américain," *Revue des deux mondes* (1896); also the writings of Ridgway, W. L. Scruggs, Sibley and G. F. Tucker, and the *Annales de jurisprudencia* (Colombia), June 1897 and following numbers. M Pradier-Fodéré, Professor of International Law at Lyons University, and formerly professor of the University of Lima, observes that "En déclarant que la grande république américaine considérerait comme dangereuse pour sa tranquillité et sa sécurité toute tentative de la part des puissances européennes d'étendre leur système politique à *une partie quelconque* du continent américain, il (le président) s'est mêlé indirectement des affaires intérieures des républiques du Nouveau Monde, autres que les États Unis; il a fait de l'intervention par anticipation et au profit de l'Union; car, c'est d'intervenir que d'interdire aux autres gouvernements d'intervenir."

South Wales, New Zealand, Queensland, Tasmania, Victoria, West Australia and South Australia as for the time being are parts of the Commonwealth, and such colonies or territories as may be admitted into or established by the Commonwealth as states; and each of such parts of the Commonwealth shall be called "a state." "Original states" shall mean "such states as are parts of the Commonwealth at its establishment." Following out this distinction between the Commonwealth and the states, articles 106 to 124 of the Commonwealth constitution deal with the respective positions of the Commonwealth, the original states, and the new states. Article 109 in particular provides that "when a law of a state is inconsistent with the law of the Commonwealth, the latter shall prevail, and the former shall, to the extent of the inconsistency, be invalid," thus paving the way for the ultimate consolidation of the federal power.

Political Science. Much has been written on the "science" of the state, or, as we prefer, in Anglo-Saxon lands, to call it, "political science." In Germany the subject is dealt with as an independent branch of university education. Several of her universities have a *staatswissenschaftliche Facultät*, granting a special degree in the subject. In consequence of the great attention paid to the subject in Germany, her state polity has been largely the work of her political writers. The result has not unnaturally tended to a system bearing some resemblance to that of the American Union, with this very important difference, however, that whereas in the United States the federal power is derived from the democratic forces of the individual states, in Germany it is derived from their aristocratic and absolutist forces. German political thinkers, in fact, have worked out *Staatsrecht* as a comparative study, in which arguments in favour of absolute government have received as much careful consideration as those in favour of democratic institutions, and the German state has developed upon lines based on the best theoretical arguments of these thinkers. There is, therefore, no anomaly in its practically absolutist government working out the most democratic reforms as yet put into legislative form. It follows, however, that German theories are of little use in the consideration of the state problems with which British and American political thinkers have to deal. Anglo-Saxon institutions are following their independent development, and if the influence of foreign institutions is felt at all, it is probably that of the clear logical detail and cohesion of French institutions.

STATE, GREAT OFFICERS OF, a designation popularly applied to all the principal ministers of the British Crown, but strictly applicable only to the lord high steward, the lord high chancellor, the lord high treasurer, the lord-president of the (privy) council, the lord (keeper of the) privy seal, the lord great chamberlain, the lord high constable, the earl marshal, and the lord high admiral. Of these, three—the lord chancellor, the lord-president of the council, and the lord privy seal—the first and second are always, and the third almost always, cabinet ministers. The offices of two more—those of the lord treasurer and the high admiral—are now executed by commission, the chief of the lords commissioners, known severally as the first lord of the treasury and the first lord of the admiralty, being likewise members of the cabinet, while the first lord of the treasury is usually at the head of the government. But, although it has become the rule for the treasury and the admiralty to be put in commission, there is nothing except usage of longer or shorter duration to prevent the Crown from making a personal appointment to either of them, and the functions which formerly appertained to the lord treasurer and the high admiral are still regularly performed in the established course of the national administration. The four offices of the high steward, the great chamberlain, the high constable, and the earl marshal stand on a different footing, and can be regarded at the present day as little else than survivals from an earlier condition of society. They have practically ceased to have any relation to the ordinary routine of business in the country or of ceremonial in the palace, and the duties associated with them have either passed entirely into abeyance or are restricted within extremely narrow limits, save on certain occasions of exceptional pomp and solemnity. All of them were once hereditary, and, taking the three kingdoms together, they or their counterparts and equivalents continue to be held by right of inheritance in one or other of them even now. These and the more important foreign great offices of state are all dealt with under their proper headings, and other information will be found in the articles CABINET, MINISTRY, PRIVY COUNCIL, TREASURY, and HOUSEHOLD, ROYAL.

On the subject of the great offices of state generally, see Stubbs, *Constitutional History*, ch. xi.; Freeman, *Norman Conquest*, ch. xxiv.; Gneist, *Constitution of England*, ch. xvi., xxv. and liv.; also Gibbon, *Decline and Fall*, ch. liii., and Bryce, *Holy Roman Empire*, ch. xiv.

STATEN ISLAND, an island constituting the borough of Richmond, New York City, and Richmond county, the southernmost of the counties of the state of New York. It is separated from Long Island on E. by the Narrows which connect Upper and Lower New York Bay; from New Jersey on the N. by the narrow channel of Kill van Kull which connects New York Bay with Newark Bay; and from New Jersey on the W. by the narrow channel of Staten Island Sound or Arthur Kill; and on its S.E. coast are Lower New York, Raritan and Prince's Bays, Great Kills, and the Atlantic Ocean. Pop. (1890), 51,693; (1900), 67,021; (1905), 72,845; (1910), 85,969. Staten Island is connected by ferry with the borough of Manhattan, 5 m. distant, and with Perth Amboy, New Jersey. The Staten Island Rapid Transit railway extends along the north shore and the south-east side, and there are several electric lines and pleasant drives. The island is triangular in shape, is $13\frac{1}{2}$ m. long from north-east to south-west, has a maximum width of nearly 8 m. at its north end, and has an area of about 70 sq. m. The north-east quarter is broken by two ranges of hills having a precipitous east slope and rising to a maximum height of about 400 ft., 1 m. inland from the Narrows; but on the west and south the hills fall gently to the Coastal Plain, which, occupying the greater part of the island, is broken only by low morainal ridges and terminates in salt marshes along much of the west coast. There are many species of forest trees and more than 1300 species of flowering plants and ferns. The climate is subject to sudden changes; but the temperature rarely rises above 90° F. or falls below zero. The island is chiefly a residential district, and in the picturesque hill section are many fine residences. Forts Wadsworth and Tompkins commanding the passage of the Narrows constitute one of the strongest defences of New York Harbor. The principal villages are New Brighton, West New Brighton, Port Richmond, Stapleton, and Tompkinsville on the north coast, and Tottenville (or Bentley Manor) on the south-west coast. Richmond, the county-seat since 1727, is a small village near the centre of the island. South Beach, below the Narrows, is a popular seaside resort. At West New Brighton is a large dyeing establishment, there are also ship-building yards, oyster fisheries, and truck farms, and among the maufactures are linoleum, paper, white lead, linseed oil, brick, and fire-clay products.

When discovered by Europeans Staten Island was occupied by the Aquehonga Indians, a branch of the Raritans, and several Indian burying-grounds, places where wampum was manufactured, and many Indian relics, including a stone head with human features, have been found here. In 1630 the Dutch West India Company granted the island to Michael Pauw as a part of his patroonship of Pavonia, and it was bought at this time from the Indians for "some duffels, kettles, axes, hoes, wampum, drilling awls, jew's harps, and divers other small wares"; but before Pauw had established a settlement upon it he sold his title back to the company. A portion of it was regranted to David Pietersen de Vries in 1636 and in 1642 the remainder was erected into a patroonship and granted to Cornelis Melyn. In 1641 de Vries established a settlement at Oude Dorp (Old Town), near Arrochar Park, near South Beach. It was destroyed by the Indians in the same year, was immediately rebuilt, was again destroyed in 1642 and was again rebuilt, but was abandoned after its destruction for the third time in 1655. A company of Waldenses founded a second settlement in 1658, at Stony Brook, about 2 m. west of the ruins of Oude Dorp; this was the principal village for many years and from 1683, when the island was erected into a county, until 1727 it was the county-seat. Melyn surrendered his rights as a patroon in 1661 and during the remainder of the Dutch régime many small grants of land were made to French, Dutch, and English settlers. In 1664 the duke of York became proprietor of the newly erected province of New York and by his grant in the same year to Berkeley and Carteret of all that portion which lay west of the Hudson river, Staten Island became properly a part of New Jersey, but in 1668 the duke decided that all islands within New York Bay which could be circumnavigated in twenty-four hours should be adjudged to New York. Captain Christopher Billopp made the trip within the time limit and was rewarded with a grant of 1163 acres at the south end of the island. He erected this into the Manor of Bentley and the manor house, built about this time, still stands in the village of Tottenville. It was in this house that Lord Howe on the 11th of September 1776 held a peace conference with Benjamin Franklin, John Adams, and Edward Rutledge representing the Continental Congress. The British army under Sir William Howe landed at the Narrows on the 3rd of July 1777 and until the close of the war Staten Island was held by the British and Loyalists. From it the British made frequent predatory raids into New Jersey and the Americans made several retaliatory raids into the island. Under the direction of General Hugh Mercer some American troops reached Richmond on the morning of the 16th of October 1776, and in an engagement which immediately followed they were victorious; but, as they were retreating with their prisoners, British reinforcements arrived and in a second engagement at Fresh Kill (now Green Ridge) they were routed with considerable loss. A second raid was made against Richmond early in August 1777; and on the 22nd of the same month American troops under General John Sullivan fought the British at several places, inflicted a loss of about 200 killed, wounded and prisoners and destroyed considerable quantities of stores. In the War of 1812 Fort Richmond was built at the Narrows and Fort Tompkins in the rear of it. The Federal government bought the site in 1847 and after destroying the old forts began the erection of the present works. In 1898 Staten Island became the borough of Richmond in Greater New York.

See I. K. Morris, *Memorial History of Staten Island* (2 vols., New York, 1898–1900); R. M. Bayles, *History of Richmond County* (New York, 1887); and J. J. Clute, *Annals of Staten Island* (New York, 1877).

STATE RIGHTS, a term used generally in political science to denote those governmental rights which belong to the individual states of a federal union, there being a certain sphere of authority in which these individual states may act without interference from the central government. Thus in the United States there were certain rights reserved to themselves by the states when forming the union under the constitution of 1787. These rights the central government is by fundamental law bound to respect, and they can be reduced only by amendment to the constitution. For a thousand years the various German states were so jealous of any curtailment of their individual rights as to prevent the formation of an efficient federal government; in Austria-Hungary the larger states still jealously guard their liberties. In federal unions, such as Mexico and Brazil where a central authority existed first and created the states, the belief in state rights is much weaker than it is in unions composed of originally independent states. The rights of a state are said to be delegated when, as in Mexico, Brazil and Colombia, the constitution is created by a central national authority which also makes the states; state rights are residuary when independent states unite to delegate by a constitution certain powers to a central government, as in the case of the German Empire, Austria-Hungary, the United States, Switzerland, and until 1905, Sweden-Norway. History shows that states forming unions of the second class are certain in after time to deny or assert that the sovereignty of the state is one of the rights reserved, according as the state belongs to a stronger or weaker section or faction; state sovereignty being the defence of the weaker state or faction, and being denied by the stronger group of states which controls the government and which asserts that a new sovereign state was created by a union of the former independent ones. This dispute is usually ended by civil war and the destruction of state sovereignty. The evolution of state rights as shown in the history of the United States is typical. Thirteen independent states formed a union in 1787 under a constitution reserving certain rights to the states. The sphere of the state authority embraced most of the powers of government, except, for instance, those relating to foreign affairs, army and navy, inter-state commerce, coinage and the tariff; the powers of the central government were specified in the fundamental law. Most of the states claimed at one time or another that sovereignty was one of the reserved rights of the states and on this theory the Southern states acted in the secession in 1861. The war that resulted destroyed all claims of state sovereignty. The other rights of the states consisted of those not delegated to the central government or forbidden to the states by the constitution. In case of doubt the presumption was in favour of the state. Since the beginning, however, the central government has gained strength at the expense of the states, seldom by direct usurpation (except during the Civil War and Reconstruction, 1861–76), but indirectly through use and custom, as the country and people developed and new conditions of government arose. The field of state rights had not increased, while centralization has slowly but surely taken place. This centralization is shown not only by the increased power and activity of the Federal government as compared with the state governments, but in the change in popular opinion indicated by the use of the terms *National*, *Union*, &c., where formerly *Confederate*, *Federal*, &c., were used, and in the use of singular verbs after the words *Congress* and the *United States*, where formerly they were followed by plural verbs.

The central authority in the United States, formerly almost unheard of by the average citizen, now touches him in many of the activities of life and sometimes intrudes even into the domain of local self-government. The history of the decay of state rights makes it seem doubtful if the federal form of government is a permanent one, or is only a transient form between independent state governments or loose confederacies and a centralized national government.

New York, 1903); A. H. Stephens, *Constitutional View of the War Between the States* (Philadelphia, 1868–1870); and A. L. Lowell, *Governments and Parties in Continental Europe* (Boston, 1896).

STATES-GENERAL, the English translation of (1) the *États-Généraux* of France before the Revolution, (2) the *Staten-Generaal* of the Dutch Netherlands. The name in both cases signifies, whatever the ultimate divergence in character of the two bodies, the assembly of the representatives of the various estates of the realm, called together for purposes of legislation or deliberation.

The French States-General.—In France the States-General owed their origin to the same causes which produced the Parliament of England, the Cortes of Spain, the Diet of the Holy Roman Empire and the Diets (*Landtage*) of the states of Germany, and they resembled these assemblies in their constitution. In these countries the royal or ducal power, when it began to extend its scope, found itself limited by the feudal system and had to turn to the forces of feudalism to obtain from them aid and counsel, *i.e.* pecuniary assistance and moral support. Instead of treating severally with the local representatives of these forces the ruler found it useful and convenient to enter into contact with them as a whole, treating with them through their principal representatives.

In France these conditions led in 1302 to a general assembly consisting of the chief lords, both lay and ecclesiastical, and the representatives of the principal privileged towns, which were like distinct lordships. There had, of course, been certain precedents before 1302 which had, as it were, paved the way for this institution; the representatives of the principal towns had several times been convoked by the king, and under Philip III. there had been assemblies of nobles and ecclesiastics in which the two orders had deliberated separately. It was the dispute between Philip IV. the Fair and Boniface VIII. which led to the States-General of 1302; the king of France desired that, in addition to the officers of the Crown, the principal authorities of the country should come and testify solemnly that they were at one with the king in this serious crisis. The letters summoning the assembly of 1302 are published by M. Georges Picot in his collection of *Documents inédits pour servir à l'histoire de France.* In 1302 the States-General had been called upon only to give *counsel* to the king; but during the same reign they were several times assembled to give him *aid*, *i.e.* to grant him subsidies, and in course of time this came to be the most frequent motive of their convocation.

In one sense the composition and powers of the States-General have always been the same. They have always included representatives of the clergy, nobility and third estate, and they have always been summoned either to grant subsidies or to advise the Crown, to give *aid and counsel.* Their composition, however, as well as their effective powers, have varied greatly at different times.

In their primitive form, *i.e.* in the 14th and the first half of the 15th centuries, the States-General had only a limited elective element. The lay lords who appeared therein were not elected, but directly chosen and summoned by the king, and the same was the case with the prelates, bishops and clergy, who were summoned *quâ* ecclesiastical lords. In the order of the clergy, however, since certain ecclesiastical bodies, *e.g.* abbeys and chapters of cathedrals, were also summoned to the assembly, and as these bodies, being persons in the moral but not in the physical sense, could not appear in person, their representative had to be chosen by the monks of the convent or the canons of the chapter. It was only the representation of the third estate which was furnished by election. Originally, moreover, the latter was not called upon as a whole to seek representation in the estates. It was only the *bonnes villes*, the privileged towns, which were called upon. They were represented by elected *procureurs*, who were frequently the municipal officials of the town, but deputies were often elected for the purpose. The country districts, the *plat pays*, were not represented.

It was during the last thirty years of the 16th century that the States-General became an entirely elective body and really representative of the whole nation as divided into three parts. This was brought about by various causes. On the one hand, the nobles and prelates who were summoned were not always inclined to attend the estates, so had themselves represented by an envoy, a *procureur*, as they had the right to do, and frequently the lords or prelates of the same district chose the same *procureur* to represent them. On the other hand, the Crown seems at that time to have felt the need of having the consent of representatives really expressing the will and feelings of all the orders, and especially of the third estate as a whole. The letters of summons to the States-General of 1484 invited the ecclesiastics, nobles and third estate in general, to meet at the chief town of their *bailliage* or *sénéchaussée* and elect deputies. An intermediate form had been employed in 1468 when the prelates and lords had still been summoned personally, but the towns had each elected three deputies, an ecclesiastic, a noble and a burgess.

At the estates of 1484 there seems to have been universal and direct suffrage for all the three orders. But the *roturiers* of the country districts could not in practice avail themselves of this power; so the country communities and small towns spontaneously elected delegates to represent them at the electoral assembly. Thus a system of indirect election arose for the third estate which became confirmed and subsequently continued to be used. To a certain extent there were sometimes more than two degrees in the suffrage; the delegates nominated by the country communities would gather together with the electors chosen by the neighbouring little town, and appoint with them new delegates to represent them at the electoral assembly of the *bailliage.* This ultimately became the system. For the clergy and nobles the suffrage remained direct; but as a rule only such ecclesiastics were admitted to the assembly of the *bailliage* as possessed a benefice, and only such lords as had a fief.

The effective powers of the States-General likewise varied in the course of time. In the 14th century they were actually great. The king could not, in theory, levy general taxation. Even in the provinces attached to the domain of the Crown, he could only levy it where he had retained the *haute justice* over the inhabitants, but not on the subjects of lords having the *haute justice.* The privileged towns had generally the right of taxing themselves. In order to obtain general taxes, the king had to obtain the consent of the lay and ecclesiastical lords and of the towns; this amounted to obtaining the authorization of the States-General, which only granted these subsidies temporarily for a fairly short period. The result was that they were summoned fairly frequently and that their power over the Crown might be considerable.

But in the second half of the 14th century certain royal taxes levied throughout the whole of the domain of the Crown, tended to become permanent, and independent of the vote of the estates. This sprang from many causes, but from one in particular; the Crown endeavoured by transforming and changing the nature of the "feudal aid" to levy a general tax by right, on its own authority, in such cases as those in which a lord could demand feudal aid from his vassals. For instance, it was in this way that the necessary taxes were raised for twenty years to pay the ransom of King John without a vote of the States-General, although they met several times during this period. Custom confined this tendency. Thus during the second half of the 15th century the chief taxes, the *taille*, aids and *gabelle* became definitely permanent for the benefit of the Crown, sometimes by the formal consent of the States-General, as in 1437 in the case of the aids. The critical periods of the Hundred Years' War had been favourable to the States-General, though at the price of great sacrifices. Under the reign of King John they had had for a few years, from 1355 to 1358, not only the voting, but through their commissaries, the administration of and jurisdiction over the taxes. In the first half of the reign of Charles VII. they had been summoned almost every year and had patriotically voted subsidies. And when the struggle was over they renounced, through weariness and a longing for peace, their most precious right, the power of the purse.

At the estates of 1484, however, after the death of Louis XI., there was a kind of awakening. The deputies of the three orders united their efforts in perfect harmony in the hope of regaining the right of periodically sanctioning taxation. They voted the *taille* for two years only, at the same time reducing it to the amount which it had reached at the end of the reign of Charles VII. They even demanded, and obtained, the promise of the Crown that they should be summoned again before the expiry of the two years. But the promise was not kept, and we do not find the States-General summoned again till 1560. There was then a first interruption of 76 years in the working of the institution, while the absolute monarchy was establishing itself. But there was a revival of its activity in the second half of the 16th century caused by the scarcity of money and the quarrels and wars of religion. The estates of Orleans in 1560, followed by those of Pontoise in 1561, and those of Blois in 1576 and 1588 were most remarkable for the wisdom, courage and efforts of the deputies, but on the whole were lacking in effect. Those of 1588 were ended on a regular *coup d'état* effected by Henry III., and the States summoned by the League, which sat in Paris in 1593 and whose chief object was to elect a Catholic king, were not a success. The States-General again met in Paris in 1614, on the occasion of the disturbances which followed the death of Henry IV.; but though their minutes bear witness to their sentiments of exalted patriotism, the dissensions between the three orders rendered them weak and they were dissolved before having completed their work, not to be summoned again till 1789.

As to the question whether the States-General formed one or three chambers for the purposes of their working, from the constitutional point of view the point was never decided. What the king required was to have the consent, the resolution of the three estates of the realm; it was in reality of little importance to him whether their resolutions expressed themselves in common or separately. At the States-General of 1484 the elections were made in common for the three orders, and the deputies also arrived at their resolutions in common. But after 1560 the rule was that each order should deliberate separately; the royal declaration of the 23rd of June 1789 even stated that they formed three distinct chambers. But Necker's report to the *conseil du roi* according to which the convocation of 1789 was decided, said (as did the declaration of the 23rd of June), that on matters of common interest the deputies of the three orders could deliberate together, if each of the others decided by a separate vote in favour of this, and if the king consented.

The working of the States-General led to an almost exclusive system of deliberation by committee, as we should say nowadays. There were, it is true, solemn general sessions, called *séances royales*, because the king presided; but at these there was no discussion. At the first, the king or his chancellor announced the object of the convocation, and set forth the demands or questions put to them by the Crown; at the other royal sessions each order made known its answers or observations by the mouth of an *orateur* elected for the purpose. But almost all useful work was done in the sections, among which the deputies of each order were divided. At the estates of 1484 they were divided into six *nations* or *sections*, corresponding to the six *généralités* then existing. Subsequently the deputies belonging to the same *gouvernement* formed a group or bureau for deliberating and voting purposes. Certain questions, however, were discussed and decided in full assembly; sometimes, too, the estates nominated commissaries in equal numbers for each order. But in the ancient States-General there was never any personal vote. The unit represented for each of the three orders was the *bailliage* or *sénéchaussée* and each *bailliage* had one vote, the majority of the deputies of the *bailliage* deciding in what way this vote should be given. At the estates of the 16th century voting was by *gouvernements*, each *gouvernement* having one vote, but the majority of the *bailliages* composing the *gouvernement* decided how it should be given.

The States-General, when they gave counsel, had in theory only a consultative faculty. They had the power of granting subsidies, which was the chief and ordinary cause of their convocation. But it had come to be a consent with which the king could dispense. We have seen how permanent taxation became established. In the 16th century, however, the estates again claimed that their consent was necessary for the establishment of new taxation, and, on the whole, the facts seem to be in favour of this view at the time. But in the course of the 17th century the principle gained recognition that the king could tax on his own sole authority. Thus were established in the second half of the 17th century, and in the 18th, the direct taxes of the *capitation* and of the *dixième* or *vingtième*, and many indirect taxes. It was sufficient for the law creating them to be registered by the *cours des aides* and the *parlements*. It was only in 1787 that the *parlement* of Paris declared that it could not register the new taxes, the land-tax and stamp-duty (*subvention territoriale* and *impôt du timbre*), as they did not know whether they would be submitted to by the country, and that the consent of the representatives of the tax-payers must be asked.

The States-General had legally no share in the legislative power, which belonged to the king alone. The States of Blois demanded, it is true in 1576, that he should be bound to turn into law any proposition voted in identical terms by each of the three orders; but the king would not grant this demand, which would not even have left him a right of veto. In practice, however, the States-General contributed largely to legislation. Those who sat in them had at all times the right of presenting complaints (*doléances*), requests and petitions to the king; in this, indeed, consisted their sole initiative. They were usually answered by an *ordonnance*, and it is chiefly through these that we are acquainted with the activity of the estates of the 14th and 15th centuries. In the latest form, and from the estates of 1484 onwards, this was done by a new and special procedure. The States had become an entirely elective assembly, and at the elections (at each step of the election if there were several) the electors drew up a *cahier des doléances* (statement of grievances) which they requested the deputies to present; this even appeared to be the most important feature of an election. The deputies of each order in every *bailliage* also brought with them a *cahier des doléances*, which was arrived at, for the third estate, by a combination of the statements drawn up by the primary or secondary electors. On the assembly of the estates the *cahiers* of the *bailliages* were incorporated into a *cahier* for each *gouvernement*, and these again into a *cahier général* or general statement, which was presented to the king, and which he answered in his council. When the three orders deliberated in common, as in 1484, there was only one *cahier général*; when they deliberated separately, there were three, one for each order. The drawing up of the *cahier général* was looked upon as the main business (*le grand œuvre*) of the session.

By this means the States-General furnished the material for numerous *ordonnances*, though the king did not always adopt the propositions contained in the *cahiers*, and often modified them in forming them into an *ordonnance*. These latter were the *ordonnances de réforme* (reforming ordinances), treating of the most varied subjects, according to the demands of the *cahiers*. They were not, however, for the most part very well observed. The last of the type was the *grande ordonnance* of 1629 (*Code Michau*) drawn up in accordance with the *cahiers* of 1614 and with the observations of various assemblies of notables which followed them.

The States-General had, however, peculiar power which was recognized, but was of a kind that could not often be exercised; it was what might be called a constituent power. The ancient public law of France contained a number of rules called "the fundamental laws of the realm (*lois fondamentales du royaume*), though most of them were purely customary; chief among them were the rules of determining the succession to the Crown and those forbidding the alienation of the domain of the Crown. The king, supreme though his power might be, could not abrogate, modify or infringe them. But it was admitted that he might do so by the consent of the States-General. The States could give the king a dispensation from a fundamental law in a given instance; they could even, in agreement with the king, make new fundamental laws. The States of Blois of 1576 and 1588 offer entirely convincing precedents in this respect. It was universally recognized that in the event of the line of Hugh Capet becoming extinct, it would be the function of the States-General to elect a new king.

The States-General of 1614 had been the last. A new convocation had indeed been announced to take place on the majority of Louis XIV., and letters were even issued in view of the elections, but this ended in nothing. Absolute monarchy was becoming definitely established, and was incompatible with the institution of the States-General. Liberal minds, however, in the *entourage* of the duke of Burgundy, who were preparing a new plan of government in view of his accession to the throne, thought of reviving the institution. It figures in the projects of St Simon and Fénelon, though the latter would have preferred to begin with an assembly of non-elected notables. But though St Simon was high in the favour of the regent Orleans, the States were not summoned at the death of Louis XIV.

In 1789 they were summoned. They were preceded, as Fénelon had wished in former days, by an assembly of notables in 1787, which already displayed great independence. It was the refusal of the *parlement* of Paris to register the fiscal edicts submitted to the Notables which led to the convocation of the States-General. The Notables, who had sat in 1787, were again summoned in 1788 to inquire into and fix the rules for the elections and the procedure of the States. Necker, in the *Mémoire* which he submitted to the *conseil du roi* in December 1788, granted for these States the *doublement du tiers, i.e.* that the third estate should have a number of deputies equal to that of the deputies of the other two orders combined, this is what had happened previously in the few provincial assemblies created by Necker during his first administration and in those created by an edict of 1787 for all the *pays d'élections*. But Necker's report, as to the subject of deliberating separately (*par ordre*) or in common, simply referred to the ancient principles; and he seems also to have proposed to maintain the system of voting by *bailliages*. Now the doubling of the *tiers* could yield it no real advantage unless the deliberation was in common and the voting by individuals, and it was this question which from the 6th of May 1789 onwards was the subject of the separate deliberations and negotiations between the three orders. On the 13th of June the third estate had arrived at a resolution to examine and settle in common the powers of the three orders, and invited to this common work those of the clergy and nobles. Certain of the latter and the majority of the clergy joined the *tiers*, and on the 17th of June it arrived at the celebrated decision by which it affirmed the principle of the national supremacy residing in the mass of the nation; the deputies, without any distinction of order, constituted a national assembly, which assembly was called upon to regenerate France by giving her a constitution, while the royal power (which in reality became provisional) could not negative its decisions. The king tried to resist. In the *séance royale* of the 23rd of June 1789, where he took the attitude of granting a *charte octroyée* (a constitution granted of the royal favour), he affirmed, subject to the traditional limitations, the right of separate deliberation for the three orders, which constitutionally formed three chambers. We know how this move failed; soon that part of the deputies of the nobles who still stood apart joined the National Assembly at the request of the king. The States-General had ceased to exist, having become the National Constituent Assembly, though it consisted of the deputies elected by the order.

See G. Picot, *Histoire des états-généraux* (2nd ed., Paris, 1888).
(J. P. E.)

The Dutch States-General.—In the Netherlands the convocation of the States-General, consisting of delegates from the provincial estates, dates from about the middle of the 15th century, under the rule of the dukes of Burgundy The name was transferred, after the separation of the northern Netherlands from the Spanish dominions, to the representatives elected by the seven sovereign provincial estates for the general government of the United Provinces. The States-General, in which the voting was by provinces—each province having one vote—was established from 1593 at the Hague. The States-General came to an end after the revolution in 1795, with the convocation of the National Assembly (March 1, 1796). See HOLLAND (*History*). The title of *Staten-Generaal* is, however, still borne by the Dutch parliament. (W. A. P.)

STATES OF THE CHURCH, or PAPAL STATES (Ital. *Stato della Chiesa, Stato Pontifico, Stato Romano, Stato Ecclesiastico;* Fr. *États de l'Église, Pontificat Souverain de Rome*, &c.; Ger. *Kirchenstaat*; in ecclesiastical Latin often *Patrimonium Sancti Petri*), that portion of central Italy which, previous to the unification of the kingdom, was under the direct government of the see of Rome. The territory stood in 1859 as in the annexed table.

With the exception of Benevento, surrounded by the Neapolitan province of Principato Ulteriore, and the small state of Pontecorvo, enclosed within the Terra di Lavoro, the States of the Church formed a compact territory, bounded on the N.W. by the Lombardo-Venetian kingdom, on the N.E. by the Adriatic, on the S.E. by the kingdom of Naples, on the S.W. by the Mediterranean, and on the W. by the grand-duchy of Tuscany and the duchy of Modena. On the Adriatic the coast extended 140 m. from the mouth of the Tronto (Truentus) to the southern mouth of the Po, and on the Tyrrhenian Sea 130 m. from 41° 20′ to 42° 22′ N. lat.

		Area in English sq. m.	Population in 1853.

	Benevento	61·3	23,176
		16,000·8	3,124,758

The divisions shown above were adopted on the 21st of December 1827, the legations being ruled by a cardinal and the delegations by a prelate. Previously the several districts formally recognized were Latium, the Marittima (or sea-board) and Campagna, the patrimony of Saint Peter, the duchy of Castro, the Orvietano, the Sabina, Umbria, the Perugino, the March of Ancona, Romagna, the Bolognese, the Ferrarese, and the duchies of Benevento and of Pontecorvo. The former papal territories are now comprised within the Italian provinces of Bologna, Ferrara, Forlì, Ravenna, Pesaro and Urbino, Ancona, Macerata, Ascoli-Piceno, Perugia, Rome and Benevento.

The question of the origin of the territorial jurisdiction of the pope is treated under PAPACY. With the moral and ecclesiastical decay of the papacy in the 9th and 10th centuries much of its territorial authority slipped from its grasp; and by the middle of the 11th century its rule was not recognized beyond Rome and the immediate vicinity. By the treaty of Sutri (February 1111) Paschal II. was compelled by the emperor Henry V. to surrender all the possessions and royalties of the Church; but this treaty was soon afterwards repudiated, and by the will of Matilda, countess of Tuscany, the papal see was enabled to lay claim to new territories of great value. By the capitulation of Neuss (1201) the emperor Otto IV. recognized the papal authority over the whole tract from Radicofani in Tuscany to the pass of Ceperano on the Neapolitan frontier—the exarchate of Ravenna, the Pentapolis, the March of Ancona, the bishopric of Spoleto, Matilda's personal estates, and the countship of Brittenoro; but a good deal of the territory thus described remained for centuries an object of ambition only on the part of the popes. The actual annexation of Ravenna, Ancona, Bologna, Ferrara, &c., dates from the 16th century. The States of the Church were of course submerged for a time by the groundswell of the French Revolution, but they appeared again in 1814. In 1849 they received a constitution. On the formation of the kingdom of Italy in 1860 they were reduced to the Comarca of Rome, the legation of Velletri, and the three delegations of Viterbo, Cività Vecchia and Frosinone; and in 1870 they disappeared from the political map of Europe. See ITALY: *History.*

STATE TRIALS, in English law, a name which primarily denotes all trials relating to offences against the state, but in practice is often used of cases illustrative of the law relating to state officers or of international or constitutional law. The first collection of accounts of state trials was published in 1719 in four volumes. Although without an editor's name, it appears that Thomas Salmon (1679–1767), an historical and geographical writer, was responsible for the collection. A second edition, increased to six volumes, under the editorship of Sollom Emlyn (1697–1754), appeared in 1730. This edition contained a lengthy preface critically surveying the condition of English law at the time. A third edition appeared in 1742, in eight volumes, the seventh and eighth volumes having been added in 1835. Ninth and tenth volumes were added in 1766, and a fourth edition, comprising ten volumes, with the trials arranged chronologically, was published the same year. A fifth edition, originated by William Cobbett, but edited by Thomas Bayly Howell (1768–1815) and known as *Cobbett's Complete Collection of State Trials*, was published between 1809 and 1826. This edition is in thirty-three volumes; twenty-one of them, giving the more important state trials down to 1781, were edited by T. B. Howell, and the remaining volumes, bringing the trials down to 1820, by his son Thomas Jones Howell (d. 1858). A new series, under the direction of a parliamentary committee, was projected in 1885, with the object of bringing the trials down to a later date. Eight volumes were published in 1888–1898, bringing the work down to 1858. The first three of these were edited by Sir J. Macdonell, the remaining five by J. E. P. Wallis. Selections have also been edited by H. L. Stephen and others. The trials are invaluable not only for their reports of criminal cases, in which the whole course of criminal procedure and evidence may be traced, but for their historical information.

STATICS (from Gr. root στα-, stand, or cause to stand), the branch of mechanics which discusses the conditions of rest or equilibrium of forces (see MECHANICS).

STATIONERY, a term embracing all the various articles sold by "stationers," who were originally booksellers having "stations" or stands in markets, near churches or other buildings for the sale of their goods (see BOOKSELLING for the further history of the word). The stationers were formed into a gild in 1403, the Livery Company not being incorporated till 1556. At the hall of the company in London, "Stationers' Hall," is kept a book for the registration of copyrights (see COPYRIGHT). The "Stationery Office" is a British government department which supplies stationery to parliament and the government offices and generally controls the printing required by them.

Under the name of stationery are now included all writing materials and implements, together with the numerous appliances of the desk and of mercantile and commercial offices.

The principal articles and operations of the stationery trade are dealt with under such headings as BOOKBINDING; COPYING MACHINES; INK; LITHOGRAPHY; PAPER; PEN; and PENCIL.

STATIONS OF THE CROSS, a series of 14 pictures or images representing the closing scenes in the Passion of Christ, viz. (1) the condemnation by Pilate, (2) the reception of the cross, (3) Christ's first fall, (4) the meeting with His mother, (5) Simon of Cyrene carrying the cross, (6) Veronica wiping the face of Jesus, (7) the second fall, (8) the exhortation to the women of Jerusalem, (9) the third fall, (10) the stripping of the clothes, (11) the crucifixion, (12) the death, (13) the descent from the cross, (14) the burial. Sometimes a 15th—the finding of the cross by Helena—is added; on the other hand in the diocese of Vienna, the stations were at the end of the 18th century reduced to eleven. They form a very popular item in Roman Catholic devotion. The representations are usually ranged round the church; sometimes they are found in the open air, especially on the ascent to some elevated church or shrine.

The devotion began among the Franciscans, who, as the guardians of the holy places in Jerusalem, sought by this means to enable Christians to make a pilgrimage at least in spirit. Pope Innocent XII. in 1694 declared that the indulgences granted for visiting Palestine might be gained by members of the order who, simply visiting the stations of the cross wherever represented, exercised a devout meditation as they passed from station to station. These indulgences were extended by Benedict XIII. in 1726 to all the faithful, and Clement XII. five years later granted the privilege to churches other than Franciscan, provided the stations were erected by a Franciscan. In 1857 the Roman Catholic bishops in England received faculties, renewed quinquenially, permitting them to erect the stations with the accompanying indulgences, and they often delegate this faculty to priests.

STATISTICS. The word "statistic" is derived from the Latin *status*, which, in the middle ages, had come to mean a "state" in the political sense. "Statistic," therefore, originally denoted inquiries into the condition of a state. Since the 18th century the denotation of the word has been extended, while at the same time its scope has become more definite, and may now be said, for all practical purposes, to be fixed.

History.—The origin of what is now known as "statistics" (Ger. *die Statistik*; Fr. *la statistique*; Ital. *statistica*) can only be referred to briefly here. As human societies became more and more highly organized, there can be no doubt that a very considerable body of official statistics must have come into existence, and been constantly used by statesmen, solely with a view to administration. The Romans were careful to obtain accurate information regarding the resources of the state, and they appear to have taken the census with a regularity which has hardly been surpassed in modern times.

Statistics, or rather the material for statistics, therefore existed at a very early period, but it was not until within the last three centuries that systematic use of the information available began to be made for purposes of investigation and not of mere administration. A volume compiled by Francesco Sansovino, entitled *Del Governo et amministrazione di diversi regni et republiche*, was printed in Venice and bears the date 1583. Other works of a similar kind were published towards the end of the 16th century in Italy and France. Works on state administration and finance continued to be published during the first half of the 17th century, and the tendency to employ figures, which were hardly used at all by Sansovino, became more marked, especially in England, where the facts connected with "bills of mortality" had begun to attract attention.

G. Achenwall is usually credited with being the first to use the word "statistics," but statistics, in the modern sense of the word, did not really come into existence until the publication (1761) by J. P. Süssmilch, a Prussian clergyman, of a work entitled *Die göttliche Ordnung in den Veränderungen des menschlichen Geschlechts aus der Geburt, dem Tode, und der Fortpflanzung desselben erwiesen.* In this book a systematic attempt was made to make use of a class of facts which up to that time had been regarded as belonging to "political arithmetic," under which description some of the most important problems of what modern writers term "vital statistics" had been studied, especially in England. Süssmilch had arrived at a perception of the advantage of studying what Quetelet subsequently termed the "laws of large numbers." He combined the method of "descriptive statistics" with that of the "political arithmeticians," who had confined themselves to investigations into the facts regarding mortality and a few other similar subjects, without much attempt at generalizing from them.

Political arithmetic had come into existence in England in the middle of the 17th century. The earliest example of this class of investigation is the work of Captain John Graunt of London, entitled *Natural and Political Annotations made upon the Bills of Mortality*, which was first published in 1666. This remarkable work, which dealt with mortality in London only, ran through many editions, and the line of inquiry it suggested was followed up by various other writers, of whom the most distinguished was Sir William Petty, who published in 1683 his *Five Essays in Political Arithmetick*. Other writers, of whom Halley, the celebrated mathematician and astronomer, was one, entered on similar investigations, and during the greater part of the 18th century the number of persons who devoted themselves to "arithmetical" inquiries into problems of the class now known as statistical was steadily increasing. Much attention was given to the construction of tables of mortality. Attempts were also made to deal with figures as the basis of political and fiscal discussion by Arthur Young, Hume and other historical writers, as well as by the two Mirabeaus.

It is now necessary to return to Süssmilch, who, as already mentioned, endeavoured to form a general theory of society, based on what were then termed "arithmetical" premises. In modern language, he made use of quantitative aggregate-observation as an instrument of social inquiry. It is true he did not enter on his investigation with an "open mind." He desired to support a foregone conclusion, as the title of his work shows. But nevertheless his work was a most valuable one, since it pointed out a road which others who had no desire to procure evidence in favour of a particular system of thought were not slow to follow. Although for many years after the appearance of Süssmilch's book there was a good deal of resistance to the introduction of "arithmetic" as the coadjutor of moral and political investigations, yet, practically there was a tacit admission of the usefulness of figures, even by the chiefs of the so-called "descriptive" school. On the other hand, Süssmilch's success was the origin of a "mathematical" school of statisticians, some of whom carried their enthusiasm for figures so far that they refused to allow any place for mere "descriptions" at all. These two schools have now coalesced, each admitting the importance of the point of view urged by the other. They were, however, still perceptibly distinct even as late as 1850, and the ignorant hostility with which many people even among the cultivated classes still regard statistical inquiries into the nature of human society may be regarded as a survival of the much stronger feeling which showed itself among "orthodox" professors of law and economics on the publication of Süssmilch's treatise.

To the impulse given by the great Belgian, Quetelet, must be attributed the foundation in 1834 of the Statistical Society of London, a body which, though it has contributed little to the theory of statistics, has had a considerable influence on the practical work of carrying out statistical investigations in the United Kingdom and elsewhere. Quetelet was above all things an exponent of the "laws of large numbers." He was especially fascinated with the tendency to relative constancy of magnitude displayed by the figures of moral statistics, especially those of crime, which inspired him with a certain degree of pessimism. His conception of an average man (*l'homme moyen*) and his disquisition on the "curve of possibility" were most important contributions to the technical development of the statistical method.

The influence exercised by Quetelet on the development of statistics is clearly seen from the fact that, though there is still considerable controversy among statisticians, the old controversy between the "descriptive" and arithmetical schools has disappeared, or perhaps we should say has been transformed into a discussion of another kind, the question now at issue being whether there is a science of statistics as well as a statistical method. It is true that a few books were published between 1830 and 1850 in which the politico-geographical description of a country is spoken of as "statistics," which is thus distinguished from "political arithmetic." The title of Knies's great work, *Die Statistik als selbständige Wissenschaft* (Cassel, 1850), is especially noteworthy as showing that the nature of the controversy was changing. Knies claimed that the really "scientific" portion of statistics consisted of the figures employed. As Haushofer says, "his starting point is political arithmetic."

Some eminent statisticians of the latter half of the 19th century accepted the view of Knies, but the majority of modern writers on the theory of statistics, especially in Germany, have adopted a slightly different standpoint according to which statistics is at once a *science* relating to the social life of man and a *method of investigation* applicable to all sciences. This view was ably maintained by von Mayr, Haushofer, Gabaglio and Block, whose views, published fifteen to twenty years before the close of last century, still substantially represent the opinions held by the majority of statisticians in Germany, and probably on the European continent. In France, however, several writers of importance have recently published works on the subject in which, in spite of the influence of M. Block, the claim of statistics to be considered as an independent sociological science has been rejected. There has been little systematic exposition of the subject in the United Kingdom. Isolated dicta have been furnished by authorities on the practice of statistics, such as the late Dr W. A. Guy, Professor J. K. Ingram, Sir Rawson W. Rawson, Sir Robert Giffen and others, Professor Foxwell has lectured on statistics at University College, London. The most important English work dealing with the matter is that of Mr A. L. Bowley. His volume, *Elements of Statistics* (first published in 1901), is intended as a practical handbook for teaching the principles on which statistics should be handled. The nature of Mr Bowley's book is, indeed, an indication of the fact that in the United Kingdom the study of statistics has been, in the main, of a practical character, the investigation of the theoretical basis of the statistical method attracting little interest. On the other hand, numerous monographs have been published by English writers on particular points connected with the technique of statistical investigation, as was natural considering the excellence of the practical use made of statistics in the United Kingdom.

With regard to the few earlier invasions of the domain of theory attempted by English writers, it may be observed that the authorities above mentioned were not unanimous. Dr Guy as well as Sir Rawson W. Rawson both claim that statistics is to be regarded as an independent science, apart from sociology, while Professor Ingram maintained that statistics cannot occupy a position co-ordinate with that of sociology, and that they "constitute only one of the aids or adminicula of science." Sir Robert Giffen has also expressed himself adversely to the continental doctrine that there is an independent science of statistics, and this opinion appears to be the correct one, but, as Dr Guy and Sir Rawson W. Rawson had the support of the great body of systematic teaching emanating from distinguished continental statisticians in support of their view, while their opponents have so far only the *obiter dicta* of a few eminent men to rely upon, it appears needful to examine closely the views held by the continental authorities, and the grounds on which they are based.

The clearest and shortest definition of the science of statistics as thus conceived is that of M. Block, who describes it as "la science de l'homme vivant en société en tant qu'elle peut être exprimée par les chiffres." He proposes to give a new name to the branch of study thus defined, namely "demography." Von Mayr's definition is longer. He defines the statistical science as "die systematische Darlegung und Erörterung der thatsächlichen Vorgänge und der aus diesen sich ergebenden Gesetze des gesellschaftlichen menschlichen Lebens auf Grundlage quantitativer Massenbeobachtungen" (the systematic statement and explanation of actual events, and of the laws of man's social life that may be deduced from these, on the basis of the quantitative observation of aggregates). Gabaglio's view is practically identical with those adopted by von Mayr and Block, though it is differently expressed. He says "statistics may be interpreted in an extended and in a restricted sense. In the former sense it is a method, in the latter a science. As a science it studies the actual social-political order by means of mathematical induction." Most German writers on the subject have endorsed the views of Block and von Mayr. Among them may be mentioned Professors J. Conrad, Lexis and Westergaard, but Dr Augst Meitzen of Berlin, a second edition of whose *Geschichte, Theorie und Technik der Statistik* was published in 1903, makes a much less wide claim. In France opinions are divided, Professors André Liesse and Fernand Faure and others accepting the view that statistics is essentially a method.

This discussion regarding the nature of statistics is to a large extent a discussion about names. There is really no difference of opinion among statistical experts as to the subject-matter of statistics, the only question being—Shall statistics be termed a science as well as a method? That there are some investigations in which statistical procedure is employed which certainly do not belong to the domain of the supposed statistical science is generally admitted. But, as already shown, an attempt has been made to claim that the phenomena of human society, or some part of those phenomena, constitute the subject-matter of an independent statistical science. It is not easy to see why this claim should be admitted. There is no reason either of convenience or logic why the use of a certain scientific method should be held to have created a science in one department of inquiry, while in others the said method is regarded merely as an aid in investigation carried on under the superintendence of a science already in existence. It is impossible to get over the fact that in meteorology, medicine, and other physical sciences statistical inquiries are plainly and obviously examples of the employment of a method, like microscopy, spectrum analysis, or the use of the telescope. Why should the fact of their employment in sociology be considered as authorizing the classification of the phenomena thus dealt with to form a new science?

The most effective argument put forward by the advocates of this view is the assertion that statistics are merely a convenient aid to investigation in the majority of sciences, but are the sole method of inquiry in the case of sociology. When, indeed, it is tested by reference to the important class of social facts which are named economic, it becomes obvious that the argument breaks down. Economics is a branch—the only scientifically organized branch—of sociology, and statistics are largely used in it, but no one, so far as we are aware, has proposed to call economics a department of statistical science.

Although, however, the above considerations forbid the acceptance of the continental opinion that the study of man in the social state is identical with statistics, it must be admitted that without statistics the nature of human society could never become known. For society is an aggregate, or rather a congeries of aggregates. Not only that, but the individuals composing these aggregates are not in juxtaposition, and what is, from the sociological point of view, the same aggregate or organ of the "body politic" is not always composed of the same individuals. Constancy of social form is maintained concurrently with the most extensive changes in the collocation and identity of the particles composing the form. A "nation" is really changed, so far as the individuals composing it are concerned, every moment of time by the operation of the laws of population. But the nation, considered sociologically, remains the same in spite of this slow change in the particles composing it, just as a human being is considered to be the same person year by year, although year by year the particles forming his or her body are constantly being destroyed and fresh particles substituted. Of course the analogy between the life of a human being and the life of a human community must not be pressed too far. Indeed, in several respects human communities more nearly resemble some of the lower forms of animal life than the more highly organized forms of animal existence. There are organisms which are fissiparous, and when cut in two form two fresh independent organisms, so diffused is the vitality of the original organism; and the same phenomenon may be observed in regard to human communities.

Now the only means whereby the grouping of the individuals forming a social organism can be ascertained, and the changes in the groups year by year observed, is the statistical method. Accordingly the correct view seems to be that it is the function of this method to make perceptible facts regarding the constitution of society on which sociology is to base its conclusions. It is not claimed, or ought not to be claimed, that statistical investigation can supply *the whole* of the facts a knowledge of which will enable sociologists to form a correct theory of the social life of man. The statistical method is essentially a mathematical procedure, attempting to give a quantitative expression to certain facts; and the resolution of differences of quality into differences of quantity has not yet been effected, even in chemical science. In sociological science the importance of differences of quality is enormous, and the effect of these differences on the conclusions to be drawn from figures is sometimes neglected, or insufficiently recognized, even by men of unquestionable ability and good faith. The majority of politicians, social "reformers" and amateur handlers of statistics generally are in the habit of drawing the conclusions that seem good to them from such figures as they may obtain, merely by treating as homogeneous quantities which are heterogeneous, and as comparable quantities which are not comparable. Even to the conscientious and intelligent inquirer the difficulty of avoiding mistakes in using statistics prepared by other persons is very great. There are usually "pit-falls" even in the simplest statistical statement, the position and nature of which are known only to the persons who have actually handled what may be called the "raw-material" of the statistics in question; and in regard to complex statistical statements the "outsider" cannot be too careful to ascertain from those who compiled them as far as possible what are the points requiring elucidation.

The Statistical Method.—This method is a scientific procedure (1) whereby certain phenomena of aggregation not perceptible to the senses are rendered perceptible to the intellect, and (2) furnishing rules for the correct performance of the quantitative observation of these phenomena. The class of phenomena of aggregation referred to includes only such phenomena as are too large to be perceptible to the senses. It does not, *e.g.* include such phenomena as are the subject-matter of microscopy. Things which are very large are often quite as difficult to perceive as those which are very small. A familiar example of this is the difficulty which is sometimes experienced in finding the large names, as of countries or provinces, on a map. Of course, the terms "large," "too large," "small" and "too small" must be used with great caution, and with a clear comprehension on the part of the person using them of the standard of measurement implied by the terms in each particular caste. A careful study of the first few pages of De Morgan's *Differential and Integral Calculus* will materially assist the student of statistics in attaining a grasp of the principles on which standards of measurement should be formed. It is not necessary that he should become acquainted with the calculus itself, or even possess anything more than an elementary knowledge of mathematical science, but it is essential that he should be fully conscious of the fact that "large" and "small" quantities can only be so designated with propriety by reference to a common standard. It is also necessary that he should be acquainted with the theory of probability as applied to statistical investigations, the need of which is well set forth by Mr A. L. Bowley in Part II. of his work, already referred to, and by other writers. Valuable instruction on this technical subject can be obtained from monographs by Professor F. Y. Edgeworth, Professor Karl Pearson, Dr John Venn, Mr Udney Yule and many other contributors to the *Transactions of the Royal Society*, the *Journal of the Royal Statistical Society*, the *Economic Journal*, the *Quarterly Journal of Economics* and similar publications in different countries.

Sources whence Statistics are Derived.—The term "statistics" in the concrete sense means systematic arrangements of figures representing "primary statistical quantities." A primary statistical quantity is a number obtained from numbers representing phenomena, with a view to enable an observer to perceive a certain other phenomenon related to the former as whole to parts. They represent either a phenomenon of existence at a given point of time or a phenomenon of accretion during a given period. As examples may be mentioned the number of deaths in a given district during *a given time*, the number of pounds sterling received by the London & North Western railway during a given time, and the number of "inches of rain" that fell at Greenwich during a given time. Other examples are the number of tons of pig-iron lying in a particular store at *a given date*, the number of persons residing (the term "residing" to be specially defined) in a given territory at a given date, and the number of pounds sterling representing the "private deposits" of the Bank of England at a given date.

Primary statistical quantities are the result of labours carried on either (A) by governments or (B) by individuals or public or private corporations.

A *Government Statistics.*—1. A vast mass of statistical material of more or less value comes into existence automatically in modern states in consequence of the ordinary administrative routine of departments. To this class belong the highly important statistical information published in England by the registrar-general, the returns of pauperism issued by the local government board, the reports of inspectors of prisons, factories, schools, and those of sanitary inspectors, as well as the reports of the commissioners of the customs, and the annual statements of trade and navigation prepared by the same officials. There are also the various returns compiled and issued by the board of trade, which is the body most nearly resembling the statistical bureaus with which most foreign governments are furnished. Most of the government departments publish some statistics for which they are solely responsible as regards both matter and form, and they are very jealous of their right to do so, a fact which is to some extent detrimental to that uniformity as to dates and periods which should be the ideal of a well-organized system of statistics. Finally may be mentioned the very important set of statistical quantities known as the budget, and the statistics prepared and published by the commissioners of inland revenue, by the post office, and by the national debt commissioners. All these sets of primary statistical quantities arise out of the ordinary work of departments of the public service. Many of them have been in existence, in some form or other, ever since a settled government existed in the country. There are records of customs receipts at London and other ports of the time of Edward III., covering a period of many years, which leave nothing to be desired in point of precision and uniformity. It may be added that many of these sets of figures are obtained in much the same form by all civilized governments, and that it is often possible to compare the figures relating to different countries and thus obtain evidence as to the sociological phenomena of each, but in regard to others there are differences which make comparison difficult.

2. Besides being responsible for the issue of what may be called administration statistics, all governments are in the habit of ordering from time to time special inquiries into special subjects of interest, either to obtain additional information needful for administrative purposes, or, in countries possessed of representative institutions, to supply statistics asked for by parliaments or congresses. It is not necessary to refer particularly to this class of statistical information, except in the case of the census. This is an inquiry of such great importance that it may be regarded as one of the regular administrative duties of governments, though as the census is only taken once in a series of years it must be mentioned under the head of occasional or special inquiries undertaken by governments. In the United Kingdom the work is done by the registrars-general who are in office when the period for taking the census comes round. On the Continent the work is carried out by the statistical bureaus of each country—except France, where it is under the supervision of the minister of the interior. The new regulations as to income-tax assessment and the new land taxes will furnish the government with much fresh information as to incomes; and the census of production ordered in the session of 1907 and already carried out as regards a number of trades will also be useful.

B. The primary statistical quantities for which individuals or corporations are responsible may be divided into three categories:

1. Among those which are compiled in obedience to the law of the land are the accounts furnished by municipal corporations, by the Bank of England, by railway, gas, water, banking, insurance and other public companies making returns to the board of trade, by trades unions, and by other bodies which are obliged to make returns to the registrar of friendly societies. The information thus obtained is published in full by the departments receiving it, and is also furnished by the companies themselves to their proprietors or members.

2. An enormous mass of statistical information is furnished voluntarily by public companies in the reports and accounts which, in accordance with their articles of association, are presented to their proprietors at stated intervals. With these statistics may be classed the figures furnished by the various trade associations, some of them of great importance, such as Lloyd's, the London Stock Exchange, the British Iron Trade Association, the London Corn Exchange, the Institute of Bankers, the Institute of Actuaries, and other such bodies too numerous to mention.

3. There are cases in which individuals have devoted themselves with more or less success to obtaining original statistics on special points. The great work done by Messrs Behm and Wagner in arriving at an approximate estimate of the population of the earth does not belong to this category, though its results are really primary statistical quantities. Many of these results have not been arrived at by a direct process of enumeration at all, but by ingenious processes of inference. It need hardly be said that it is not easy for individuals to obtain the materials for any primary statistical quantity of importance, but it has been done in some cases with success. The investigations of Mr Charles Booth into labour and wages questions, carried out with care over many years, are a remarkable example of this.

Operations Performed on Primary Statistical Quantities.—Only a brief description of matters connected with the *technique* of the statistical method can be given in this article. In order to form statistics properly so called the primary statistical quantities must be formed into tables, and in the formation of these tables lies the art of the statistician. It is not a very difficult art when the principles relating to it have been properly grasped, but those who are unfamiliar with the subject are apt to underrate the difficulty of correctly practising it.

Simple Tables.—The first thing to be done in the construction of a table is to form a clear idea of what the table is to show, and to express that idea in accurate language. This is a matter which is often neglected, and it is a source of much waste of time and occasionally of misapprehension to those who have to study the figures thus presented. No table ought to be considered complete without a "heading" accurately describing its contents, and it is frequently necessary that such headings should be rather long. It has been said that "you can prove anything by statistics." This statement is, of course, absurd, taken absolutely, but, like most assertions which are widely believed, it has a grain of truth in it. If this popular saying ran "you can prove anything by tables with slovenly and ambiguous headings," it might be assented to without hesitation. The false "statistical" facts which obtain a hold of the public mind may often be traced to some widely circulated table, to which, either from stupidity or carelessness, an erroneous or inaccurate "heading" has been affixed.

A statistical table in its simplest form consists of "primaries" representing phenomena of the same class, but existing at different points of time, or coming into existence during different portions of time. This is all that is essential to a table, though other things are usually added to it as an aid to its comprehension. A table stating the number of persons residing in each county of England on a given day of a given year, and also, in another column, the corresponding numbers for the same counties on the corresponding day of the tenth year subsequently, would be a simple tabular statement of the general facts regarding the total population of those counties supplied by two successive censuses. Various figures might, however, be added to it which would greatly add to its clearness. There might be columns showing the increase or decrease for each county and for the whole kingdom during the ten years, and another column showing what *proportion*, expressed in percentages, these increases or decreases bore to the figures for the earlier of the two years. Then there might be two columns showing what proportions, also expressed as percentages, the figures for each county bore in each year to the figures for the whole kingdom. The nine-column table thus resulting would still be simple, all the figures being merely explicit assertions of facts which are contained implicitly in the original "primaries."

Complex Tables.—Suppose now we have another table precisely similar in form to the first, and also relating to the counties of England, but giving the number of houses existing in each of them at the same two dates. A combination of the two would form a complex table, and an application of the processes of arithmetic would make evident a number of fresh facts, all of which would be implied in the table, but would not be obvious to most people until explicitly stated.

The technical work of the statistician consists largely in operations of which the processes just referred to are types.

Proportions.—The most usual and the best mode of expressing the proportion borne by one statistical quantity to another is to state it as a percentage. In some cases another method is adopted, viz. that of stating the proportion in the form "one in so many." This method is generally a bad one, and its use should be discouraged as much as possible, the chief reason being that the changing portion of this kind of proportional figure becomes greater or less inversely, and not directly, as the phenomenon it represents increases or diminishes.

Averages.—Averages or means are for statistical purposes divided into two classes, the *arithmetical* and *weighted.* An arithmetical mean is the sum of all the members forming the series of figures under consideration divided by their number, without reference to their **weight** or relative importance among themselves. A weighted mean is the sum of such figures divided by their number, with due allowance made for their weight. An example will make this clear, and the simplest example is taken from a class of statistical quantities of a peculiar kind, viz. *prices*. The price of a given article is the approximate mathematical expression of the rates, in terms of money, at which exchanges of the article for money were actually made at or about a given hour on a given day. A *quotation of price* such as appears in a daily price list is, if there has been much fluctuation, only a very rough guide to the actual rates of exchange that have been the basis of the successive bargains making up the day's business. But let us suppose that the closing price each day may be accepted as a fair representative of the day's transactions, and let us further suppose that we desire to obtain the *average* price for thirty days. Now, the sum of the prices in question divided by thirty would be the arithmetical mean, and its weak point would be that it made no allowance for the fact that the business done on some days is much larger than that done on others; in other words, it treats them as being all of equal weight. Now if, as is actually the case in some markets, we have a daily account of the *total quantities sold* we can weight the members accurately, and can then obtain their weighted mean. There are cases in which the careless use of arithmetical means misleads the student of the social organism seriously. It is often comparatively easy to obtain arithmetical means, but difficult to obtain weighted means. Inferences based on the former class of average should be subjected to the most rigid investigation.

There are many methods of weighting averages; for descriptions of these statistical processes the reader must be referred to the works on the technique of statistics. In chapter v. of Mr Bowley's volume, the subject is dealt with in a manner suitable for students.

Before closing this short survey of the very important subject of averages or means, it is needful to discuss briefly the nature of the phenomena which they may safely be regarded as indicating, when they have been properly obtained. Given a weighted mean of a series of numbers referring to no matter what phenomenon, it is obvious that the value of the mean as a *type* of the whole series will depend entirely on the extent of divergence from it of the members of the series as a body. If we are told that there are in a certain district 1000 men, and that their average height is 5 ft. 8 in., and are told nothing further about them, we can make various hypotheses as to the structure of this body from the point of view of height. It is possible that they may consist of a rather large number of men about 6 ft. high, and a great many about 5 ft. 5 in. Or the proportions of relatively tall and short men may be reversed, that is, there may be a rather large number of men about 5 ft. 4 in., and a moderate number of men about 5 ft. 11 in. It is also possible that there may be very few men whose height is exactly 5 ft. 8 in., and that the bulk of the whole body consists of two large groups—one of giants and the other of dwarfs. Lastly, it is possible that 5 ft. 8 in. may really give a fair idea of the height of the majority of the men, which it would do if (say) 660 of them were within an inch of that height, either by excess or deficiency, while of the remainder one half were all above 5 ft. 9 in. and the other half all below 5 ft. 7 in. This latter supposition would most likely be found to be approximately correct if the men belonged to a race whose average height was 5 ft. 8 in., and if they had been collected by chance. The extent of the divergence of the items composing an average from the average itself may be accurately measured and expressed in percentages of the average, the algebraic signs + and − being employed to indicate the direction of the variation from the mean. An average may, therefore, advantageously be supplemented: (1) by a figure showing what proportion of the members from which it is derived differs from the average by a relatively small quantity, and (2) by figures showing the maximum and minimum deviations from the average. The meaning of the term "relatively small" must be considered independently in each investigation. Fuller remarks on averages will be found in the works mentioned at the conclusion of this article.

Prices.—Reference has already been made to the peculiar class of statistical quantities known as *prices*. Prices in their widest sense include all figures expressing *ratios of exchange*. In modern society the terms of exchange are always expressed in money, and the things for which money is exchanged are: (1) concrete entities with physical attributes, such as iron or wheat; (2) immediate rights, such as those given by interest-bearing securities of all kinds, by bills of exchange, by railway or steamship contracts to carry either passengers or goods, and by bargains relative to the foreign exchanges; (3) contingent rights, such as those implied in policies of insurance. All these rates of exchange belong to the same category, whether they are fixed within certain limits by law, as in the case of railway charges, or are left to be determined by the "higgling of the market." All these cases of price may conceivably come within the operation of the statistical method, but the only matter connected with price which it is necessary to refer to here is the theory of the *index number*.

Index Numbers.—The need for these became conspicuous during the investigations of Tooke, Newmarch and others into the general cyclical movements of the prices of commodities; and to construct a good system of these may be said to be one of the highest technical aims of the statistical method. In comparing the prices of different years it was soon observed that, though whole groups of articles moved upwards or downwards simultaneously, they did not all move in the same proportion, and that there were nearly always cases in which isolated articles or groups of articles moved in the opposite direction to the majority of articles. The problem presented to statisticians therefore was, and is, to devise a statistical expression of the general movement of prices, in which all prices should be adequately represented. The first rough approximation to the desired result was attained by setting down the percentages representing the movements, with their proper algebraic signs before them, and adding them together algebraically. The total with its proper sign was then divided by the number of articles, and the quotient represented the movement in the prices of the whole body of articles during the period under consideration. It was soon seen, however, that this procedure was fatally defective, inasmuch as it treated all prices as of equal weight. Cotton weighed no more than pimento, and iron no more than umbrellas. Accordingly an improvement was made in the procedure, first by giving the prices of several different articles into which cotton, iron and other important commodities entered, and only one price each in the case of the minor articles, and secondly by fixing on the price of some one article representing iron or cotton, and multiplying it by some number selected with the view of assigning to these articles their proper weights relatively to each other and to the rest. The objection to both these plans is the same—that the numbers attached to the various articles or groups of articles are purely arbitrary; and attempts have been made to obtain what may be called *natural* index numbers, the most successful so far being that of Sir Robert Giffen, whose index numbers were obtained from the declared values of the imports or exports into or from the United Kingdom of the articles whose prices are dealt with. In the case of both imports and exports Sir Robert worked out the proportion borne by the value of each article to the total value for a series of years. Deducting the "unenumerated" articles, a series of numbers was thus obtained which could be used as the means of weighting the prices of the articles in an investigation of a movement of prices. This procedure is no doubt susceptible of further improvement, like its predecessors. The index numbers prepared and published every month by the *Economist*, and by Mr Augustus Sauerbeck, which are weighted, are of great value; owing to the frequency of their appearance they make it possible to watch the tendency of prices closely.

The Desirability of Increased Uniformity in Statistics.—One of the most serious difficulties in connexion with statistical investigations is the variety of the modes in which primaries of the same order are obtained, as regards dates and periods. This is a matter of which all persons who have occasion to use statistics are made painfully aware from time to time. Some attempts have lately been made to introduce more harmony into the official statistics of the United Kingdom, and many years ago a committee of the treasury sat to inquire into the matter. The committee received a good deal of evidence, and presented a report, from which, however, certain members of the committee dissented, preferring to express their views separately. The evidence will be found very interesting by all who wish to obtain an insight into the genesis of the official statistics of the country.

The International Institute of Statistics.—The absence of uniformity in statistics which is felt in England is not so marked in foreign countries, where the principle of centralization in arrangements of a political character is more powerful. In several continental countries and in the United States there are statistical bureaus with definite duties to perform. In the United Kingdom, as already remarked, the nearest approach to a central statistical office is the commercial and statistical department of the board of trade, on which the work of furnishing such statistics as are not definitely recognized as within the province of some other state department usually falls. Various attempts have been made to introduce more uniformity into the statistics of all countries. It was with this object that statistical congresses have met from time to time since 1853. An endeavour was made at the congress held in 1876 at Budapest to arrange for the publication of a system of international statistics, each statistical bureau undertaking a special branch of the subject. The experiment was, however, foredoomed to be only a very partial success, first because all countries were not then and are not yet furnished with central statistical offices, and secondly because the work which fell on the offices in existence could only be performed slowly, as the ordinary business of the offices necessarily left them little leisure for extra work. In 1885, at the jubilee of the London Statistical Society, a number of eminent statistical officials from all parts of the world except Germany were present, and the opportunity was taken to organize an International Institute of Statistics with a view to remedying the defects already ascertained to exist in the arrangements made by the congresses. The only obstacle to securing a proper representation of all countries was the absence of any German delegates, none of the official heads of the German statistical office being allowed to attend—apparently on political grounds. Since then assurances of a satisfactory kind have been given to the German government that their servants would be in no way committed to any course disapproved by that government if they gave their assistance to the Institute, from the formation of which it is hoped that much advantage may result. For information as to the constitution and objects of the Institute reference may be made to a paper by the late Dr F. X. von Neumann-Spallart in vol. i. (1886) of the *Bulletin de l'institut international de statistique* (Rome, 1886). Meetings of the Institute have been held annually ever since its formation in various cities of the world.

(W. Ho.)

STATIUS, PUBLIUS PAPINIUS (*c.* A.D. 45–96), Latin poet, was born at Naples. He was, to a great extent, devoted by birth and training to the profession of a poet. The Statii were of Graeco-Campanian origin, and were of gentle extraction, though impoverished, and the family records were not without political distinctions. The poet's father taught with marked success at Naples and Rome, and from boyhood to age he proved himself a champion in the poetic tournaments which formed an important part of the amusements of the early empire. The younger Statius declares that his father was in his time equal to any literary task, whether in prose or verse. Probably the poet inherited a modest competence and was not under the necessity of begging his bread from wealthy patrons. He certainly wrote poems to order (as *Silvae*, i. 1, 2, ii. 7, and iii. 4), but there is no indication that the material return for them was important to him, in spite of an allusion in Juvenal's seventh satire. Of events in the life of Statius we know little. From his boyhood he was victorious in poetic contests—many times at his native city Naples, thrice at Alba, where he received the golden crown from the hand of the emperor Domitian. But at the great Capitoline competition (probably on its third celebration in 94 A.D.) Statius failed to win the coveted chaplet of oak leaves. No doubt the extraordinary popularity of his *Thebais* had led him to regard himself as the supreme poet of the age, and when he could not sustain this reputation in the face of rivals from all parts of the empire he accepted the judges' verdict as a sign that his day was past, and retired to Naples, the home of his ancestors and of his own young years. We still possess the poem he addressed to his wife on this occasion (*Silv.* iii. 5). There are hints in this poem which naturally lead to the surmise that Statius was suffering from a loss of the emperor's favour; he may have felt that a word from Domitian would have won for him the envied garland, and that the word ought to have been given. In the preface to book iv. of the *Silvae* there is mention of detractors who hated our poet's style, and these may have succeeded in inducing a new fashion in poetry at court. Such an eclipse, if it happened, must have cut Statius to the heart. He appears to have relished thoroughly the rôle of court-poet. The statement sometimes made that the elder Statius had been the emperor's teacher, and had received many favours from him, so that the son inherited a debt of gratitude, seems to have no solid foundation. Statius lauds the emperor, not to discharge a debt, but rather to create an obligation. His flattery is as far removed from the gentle propitiatory tone of Quintilian as it is from the coarse and crawling humiliation of Martial. It is in the large extravagant style of a nature in itself healthy and generous, which has accepted the theme and left scruples behind. In one of his prefatory epistles Statius declares that he never allowed any work of his to go forth without invoking the godhead of the divine emperor. Statius had taken the full measure of Domitian's gross taste, and, presenting him with the rodomontade which he loved, puts conscience and sincerity out of view, lest some uneasy twinge should mar his master's enjoyment. But in one poem, that in which the poet pays his due for an invitation to the Imperial table, we have sincerity enough. Statius clearly feels all the raptures he expresses. He longs for the power of him who told the tale of Dido's banquet, and for the voice of him who sang the feast of Alcinous, that he may give forth utterance worthy of the lofty theme. The poet seemed, he says, to dine with great Jove himself and to receive nectar from Ganymede the cup-bearer (an odious reference to the imperial favourite Earinus). All his life hitherto has been barren and profitless. Now only has he begun to live in truth. The palace struck on the poet's fancy like the very hall of heaven; nay, Jove himself marvels at its beauty, but is glad that the emperor should possess such an earthly habitation; he will thus feel less desire to seek his destined abode among the immortals in the skies. Yet even so gorgeous a palace is all too mean for his greatness and too small for his vast presence. "But it is himself, himself, that my eager eye has alone time to scan. He is like a resting Mars or Bacchus or Alcides." Martial too swore that, were Jove and Domitian both to invite him to dinner for the same day, he would prefer to dine with the greater potentate on the earth. Martial and Statius were no doubt supreme among the imperial flatterers. Each was the other's only serious rival. It is therefore not surprising that neither should breathe the other's name. Even if we could by any stretch excuse the bearing of Statius towards Domitian, he could never be forgiven the poem entitled "The Hair of Flavius Earinus," Domitian's Ganymede (*Silv.* iii. 4), a poem than which it would be hard to find a more repulsive example of real poetical talent defiled for personal ends. Everything points to the conclusion that Statius did not survive his emperor—that he died, in fact, a short time after leaving Rome to settle in Naples. Apart from the emperor and his minions, the friendships of Statius with men of high station seem to have been maintained on fairly equal terms. He was clearly the poet of society in his day as well as the poet of the court.

As poet, Statius unquestionably shines in many respects when compared with most other post-Augustans. He was born with exceptional talent, and his poetic expression is, with all its faults, richer on the whole and less forced, more buoyant and more felicitous, than is to be found generally in the Silver Age of Latin poetry. Statius is at his best in his occasional verses, the *Silvae*, which have a character of their own, and in their best parts a charm of their own. The title was proper to verses of rapid workmanship, on everyday themes. Statius prided himself on his powers of improvisation, and he seems to have been quite equal to the feat, which Horace describes, of dictating two hundred lines in an hour while standing on one leg. The improvisatore was in high honour among the later Greeks, as Cicero's speech for the poet Archias indicates; and the poetic contests common in the early empire did much to stimulate ability of the kind. It is to their velocity that the poems owe their comparative freshness and freedom, along with their loose texture and their inequality. There are thirty-two poems, divided into five books, each with a dedicatory epistle. Of nearly four thousand lines which the books contain, more than five-sixths are hexameters. Four of the pieces (containing about 450 lines) are written in the hendecasyllabic metre, the "tiny metre of Catullus," and there is one Alcaic and one Sapphic ode. The subjects of the *Silvae* are very various. Five poems are devoted to flattery of the emperor and his favourites; but of these enough has already been said. Six are lamentations for deaths, or consolations to survivors. Statius seems to have felt a special pride in this class of his productions; and certainly, notwithstanding the excessive and conventional employment of pretty mythological pictures, with other affectations, he sounds notes of pathos such as only come from the true poet. There are oftentimes traits of an almost modern domesticity in these verses, and Statius, the childless, has here and there touched on the charm of childhood in lines for a parallel to which, among the ancients, we must go, strange to say, to his rival Martial. One of the *epicedia*, that on Priscilla the wife of Abascantus, Domitian's freedman (*Silv.* v. 1), is full of interest for the picture it presents of the official activity of a high officer of state. Another group of the *Silvae* give picturesque descriptions of the villas and gardens of the poet s friends. In these we have a more vivid representation than elsewhere of the surroundings amid which the grandees of the early empire lived when they took up their abode in the country. It was of these pieces that Niebuhr thought when he said that the poems of Statius are charming to read in Italy. They exhibit, better even than Pliny's well-known letters, the passion of the rich Roman for so constructing his country house that light, air, sun and leafage should subserve his luxury to the utmost, while scope was left for displaying all the resources of art which his wealth enabled him to command. As to the rest of the *Silvae*, the congratulatory addresses to friends are graceful but commonplace, nor do the jocose pieces call for special mention here. In the "Kalendae decembres" we have a striking description of the gifts and amusements provided by the emperor for the Roman population on the occasion of the Saturnalia. In his attempt at an epithalamium (*Silv.* i. 2) Statius is forced and unhappy. But his birthday ode in Lucan's honour (*Silv.* ii. 7) has, along with the accustomed exaggeration, many powerful lines, and shows high appreciation of preceding Latin poets. Some phrases, such as "the untaught muse of high-souled Ennius" and "the lofty passion of sage Lucretius," are familiar words with all scholars. The ode ends with a great picture of Lucan's spirit rising after death on wings of fame to regions whither only powerful souls can ascend, scornfully surveying earth and smiling at the tomb, or reclining in Elysium and singing a noble strain to the Pompeys and the Catos and all the "Pharsalian host," or with proud tread exploring Tartarus and listening to the wailings of the guilty, and gazing at Nero, pale with agony as his mother's avenging torch glitters before his eyes. It is singular to observe how thoroughly Nero had been struck out of the imperial succession as recognized at court, so that the "bald Nero" took no umbrage when his flatterer-in-chief profanely dealt with his predecessor's name.

The epic poems of Statius are less interesting because cast in a commoner mould, but they deserve study in many respects. They are the product of long elaboration. The *Thebais*, which the poet says took twelve years to compose, is in twelve books, and has for its theme the old "tale of Thebes"—the deadly strife of the Theban brothers. There is also preserved a fragment of an *Achilleis*, consisting of one book and part of another. In the weary length of these epics there are many flowers of pathos and many little finished gem-pictures, but the trammels of tradition, the fashionable taste and the narrow bars of education check continually the poet's flight. Not merely were the materials for his epics prescribed to him by rigid custom, but also to a great extent the method by which they were to be treated. All he could do was to sound the old notes with a distinctive *timbre* of his own. The gods must needs wage their wonted epic strife, and the men, their puppets, must dance at their nod; there must needs be heavenly messengers, portents, dreams, miracles, single combats, similes, Homeric and Virgilian echoes, and all the other paraphernalia of the conventional epic. But Statius treats his subjects with a boldness and freedom which contrast pleasingly with the timid traditionalism of Silius Italicus and the stiff scholasticism of Valerius Flaccus. The vocabulary of Statius is conspicuously rich, and he shows audacity, often successful, in the use of words and metaphors. At the same time he carried certain literary tricks to an aggravating pitch, in particular the excessive use of alliteration, and the misuse of mythological allusion. The most well-known persons and places are described by epithets or periphrases derived from some very remote connexion with mythology, so that many passages are as dark as Heraclitus. The *Thebais* is badly constructed. The action of the epic is hindered and stopped by enormous episodes, one of which fills one-sixth of the poem. Nor had Statius a firm grasp or clear imagination of character. So trying are the late ancient epics to a modern reader that he who has read any one of the three—Statius, Silius and Valerius Flaccus (Lucan stands apart)—will with difficulty be persuaded to enter on the other two. Yet, if he honestly reads them all, he can hardly fail to rank Statius the highest of the three by a whole sphere.

The *editio princeps* of the epics is dated 1470, of the *Silvae* 1472. Notable editions since have been those of Bernartius (Antwerp, 1595), Gronovius (1653) and Barth (1664). Recent texts are the Teubner (the *Achilleis* and *Thebais* by Kohlmann, the *Silvae* by Baehrens) and that contained in the new edition of the *Corpus poetarum latinorum*; and of the *Silvae* only, texts by Klotz (1899), and Vollmer (1898), the last with an explanatory commentary. Among editions of portions of Statius's works, that of the *Silvae* by Jeremiah Markland, fellow of Peterhouse in Cambridge (1728), deserves special attention. A translation of the *Silvae* with introduction and notes was published by D. A. Slater in 1908 (Oxford Library of Translations). A critical edition of the *Thebais* and *Achilleis* was begun by O. Müller (1870) but not completed. The condition of the text of the *Silvae* is one of the most curious facts in the history of ancient literature. Poggio discovered a MS. at St Gallen and brought it into Italy. This MS. has disappeared, but from it are derived all our existing MSS., except one of the birthday ode to Lucan, now at Florence, and of the 10th century. Politian collated Poggio's MS. with the *editio princeps*, and the collation has come down to us, and is the principal basis of the text. The MSS. of the epics are numerous, as was to be expected from their great popularity in the middle ages, to which Dante is witness (see *Purg.* xxi., where an interview with the shade of Statius is described at some length). (J. S. R.)

STATUTE, a law made by the "sovereign power" in the state (see Act of Parliament). It forms a part of the *lex scripta*, or written law, which by English legal authorities is used solely for statutory law, a sense much narrower than it bore in Roman law. To make a statute the concurrence of the Crown and the three estates of the realm is necessary. Thus a so-called statute of 5 Ric. II. c. 5, directed against the Lollards, was afterwards repudiated by the Commons as passed without their assent. The validity of a statute was indeed at times claimed for ordinances such as that just mentioned, not framed in accordance with constitutional rule, and was actually given to royal proclamations by 31 Hen. VIII. c. 8 (1539). But this act was repealed by 1 Edw. VI. c. 12, and since that time nothing but a statute has possessed the force of a statute, unless indeed certain rules or orders depending ultimately for their sanction upon a statute may be said to have such force. Examples of what may be called indirect legislation of this kind are orders in council (see Privy Council), by-laws made under the powers of the Public Health Acts, Municipal Corporation Acts and other Acts, and rules of court such as those made under the powers of the Judicature Acts and Acts of Sederunt of the Court of Session.

The list of English statutes as at present existing begins with the Statute of Merton, 1235.[1] Many of the earlier statutes are known by the names of the places at which they were passed, *e.g.* the Statutes of Merton, Marlbridge, Gloucester, Westminster, or by their initial words, *e.g. Quia Emptores, Circumspecte Agatis.* The earliest existing statute roll is 6 Edw. I. (the Statute of Gloucester). After 4 Hen. VII. the statute roll ceased to be made up, and enrolments in chancery (first made in 1485) take its place. Some of the acts prior to the Statute of Gloucester are of questionable authority, but have gained recognition by a kind of prescription.

All statutes were originally public, irrespective of their subject-matter. The division into public and private dates from the reign of Richard III. At present statutes are of four kinds, public general acts, public local and personal acts, private acts printed by the king's printers and private acts not so printed. The division into public general and public local and personal rests upon a resolution of both Houses of Parliament in 1798. In 1815 a resolution was passed in accordance with which private acts are printed, with the exception of name, estate, naturalization and divorce acts. The last two are now practically superseded by the provisions of the Divorce Act 1857 (except as to Ireland and India), and the Naturalization Act 1870. Since 1815 it has been usual to refer to public general acts by Arabic numerals, *e.g.* 3 Edw. VII. c. 21, public local and personal acts by small Roman numerals, *e.g.* 3 Edw. VII. c. xxi. Each act is strictly but a chapter of the legislation of the session, which is regarded as composing a single act divided into chapters for convenience, the chapters themselves being also called acts. The citation of previous acts is provided for by 13 and 14 Vict. c. 21, § 3. It is now usual for each chapter or act to contain a short title by which it may be cited, *e.g.* the Elementary Education Act 1870. The Short Titles Act 1892 created short titles for numerous single acts and groups of acts, and since then it has been usual to cite acts and groups by their short titles—where possible—

[1] Ruffhead's edition of the statutes begins with the Magna Carta of 1225. But in the *Revised Statutes* that form of Magna Carta which is now law appears as a statute of the year 1297. It is often known as *Confirmatio cartarum*, and is a recital and confirmation by Edward I. of the chief provisions of John's charter.

rather than by the year of the reign. 8 & 9 Vict. c. 113, s. 3, makes evidence the king's printers' copies of private and local and personal acts. A private act not printed by the king's printers is proved by an examined copy of the parliament roll.

A public act binds all subjects of the realm, and need not be pleaded (except where the law from motives of policy specially provides for pleading certain acts, as in the defences of not guilty by statute, the Statute of Frauds and the Statute of Limitations). A private act must generally be pleaded, and does not as a rule bind strangers to its provisions. Formerly an act took effect from the first day of the session in which it was passed. The hardship caused by this technical rule has been obviated by 33 Geo. III. c. 13, by which an act takes effect from the day on which it receives the royal assent, where no other date is named. This has been held to mean the beginning of the day, so as to govern all matters occurring on that day. An act cannot in the strict theory of English law become obsolete by disuse. Nothing short of repeal can limit its operation. The law has, however, been interpreted in many cases with somewhat less rigour. In the case of a prosecution for blasphemy in 1883 (*R.* v. *Ramsay*) Lord Coleridge said, "though the principles of law remain unchanged, yet (and it is one of the advantages of the common law) their application is to be changed with the changing circumstances of the times."[1] This would be applicable as much to the interpretation of statutes as to other parts of the common law. The title, preamble and marginal notes are strictly no part of a statute, though they may at times aid its interpretation.

Besides the fourfold division above mentioned, statutes are often classed according to their subject-matter, as perpetual and temporary, penal and beneficial, imperative and directory, enabling and disabling. Temporary acts are those which expire at a date fixed in the act itself. Thus the Army Act is passed annually and continues for a year; the Ballot Act 1872 expired at the end of 1880, and the Regulation of Railways Act 1873 at the end of five years. By means of these temporary acts experimental legislation is rendered possible in many cases where the success of a new departure in legislation is doubtful. In every session an Expiring Laws Continuance Act is passed for the purpose of continuing (generally for a year) a considerable number of these temporary acts. By 48 Geo. III. c. 106 a continuing act is to take effect from the date of the expiration of a temporary act, where a bill for continuing the temporary act is in parliament, even though it be not actually passed before the date of the expiration. Penal acts are those which impose a new disability; beneficial, those which confer a new favour. An imperative statute (often negative or prohibitory in its terms) makes a certain act or omission absolutely necessary, and subjects a contravention of its provisions to a penalty. A directory statute (generally affirmative in its terms) recommends a certain act or omission, but imposes no penalty on non-observance of its provisions. To determine whether an act is imperative or directory the act itself must be looked at, and many nice questions have arisen on the application of the rule of law to a particular case. Enabling statutes are those which enlarge the common law, while disabling statutes restrict it. This division is to some extent coincident with that into beneficial and penal. Declaratory statutes, or those simply in affirmance of the common law, were at one period not uncommon, but they are now practically unknown. The Treason Act 1351 is an example of such a statute. Statutes are sometimes passed in order to overrule specific decisions of the courts. Examples are the Factors Act 1877, the Territorial Waters Jurisdiction Act 1878, the Married Women's Property Act 1893, the Trade Disputes Act 1906.

The construction or interpretation of statutes depends partly on the common law, partly on statute. The main rules of the common law, as gathered from the best authorities, are these: (1) Statutes are to be construed, not according to their mere letter, but according to the intent and object with which they were made. (2) The relation of the statute to the common law is to be considered. In the words of the resolution of the Court of Exchequer in *Heydon's case*, 3 Coke's Rep. 7, the points for consideration are: "(*a*) What was the common law before the making of the act? (*b*) What was the mischief and defect against which the common law did not provide? (*c*) What remedy the parliament hath resolved and appointed to cure the disease of the Commonwealth? (*d*) The true reason of the remedy." (3) Beneficial or remedial statutes are to be liberally, penal more strictly, construed. (4) Other statutes *in pari materia* are to be taken into consideration. (5) A statute which treats of persons of inferior rank cannot by general words be extended to those of superior rank. (6) A statute does not bind the Crown, unless it be named therein. (7) Where the provision of a statute is general, everything necessary to make such provision effectual is implied. (8) A later statute repeals an earlier, as far as the two are repugnant, but if they may stand together repeal will not be presumed. (9) There is a presumption against creation of new or ousting of existing jurisdictions, against impairing obligations, against retrospective effect, against violation of international law, against monopolies, and in general against what is inconvenient or unreasonable. (10) If a statute inflicts a penalty, the penalty implies a prohibition of the act or omission to which the penalty is imposed. Whether the remedy given by statute is the only one depends on the words of the particular act. In some cases an action or an indictment will lie; in others the statutory remedy, generally summary, takes the place of the common law remedy. In some instances the courts have construed the imposition of a penalty as operating not to invalidate a contract but to create a tax upon non-compliance with the terms of the statute. The Interpretation Act 1889 provides an authentic interpretation for numerous words and phrases of frequent occurrence in statutes. In addition to these general provisions most statutes contain an interpretation clause or interpretation clauses dealing with special words or phrases. A very detailed example is s. 742 of the Merchant Shipping Act 1894.

The earlier acts are generally simple in character and language, and comparatively few in number. At present the number passed every session is enormous; in the session of 1906 it was 58 general and 212 local and personal acts, the former being under the average. Without going as far as to concede with an eminent legal authority that of such legislation three-fourths is unnecessary and the other fourth mischievous, it may be admitted that the immense library of the statutes would be but a trackless desert without trustworthy guides. Revision of the statutes was evidently regarded by the legislature as desirable as early as 1563 (see the preamble to 5 Eliz. c. 4). It was demanded by a petition of the Commons in 1610. Both Coke and Bacon were employed for some time on a commission for revision. In 1861 was passed the first of a long series of Statute Law Revision Acts. The most important action, however, was the nomination of a revision committee by Lord Chancellor Cairns in 1868, the practical result of which has been the issue of an edition of the *Revised Statutes* in eighteen volumes, bringing the revision of statute law down to 1886. This edition is of course subject to the disadvantage that it becomes less accurate every year as new legislation appears. *A Chronological Table and Index of the Statutes* which are still law is published from time to time by the council of law reporting.

The chief editions of the British statutes are the *Statutes of the Realm* printed by the king's printers, Ruffhead's and the fine folio edition issued from 1810 to 1824 in pursuance of an address from the House of Commons to George III.

AUTHORITIES.—The safest authority is of course the *Revised Statutes*. Chitty's collection of *Statutes of Practical Utility* is a useful compilation. Among the earlier works on statute law may be mentioned the readings and commentaries on statutes by great lawyers, such as the second volume of Coke's *Institutes*, Bacon's *Reading on the Statute of Uses*, Barrington's *Observations on the more ancient Statutes from Magna Carta to the 21 Jac. I. c. 27* (5th ed., 1796), and the Introduction to Blackstone's *Commentaries*. Among the later works are the treatises of Dwarris (2nd ed., 1848) and Sir P. B. Maxwell (3rd ed., 1905) and Hardcastle (3rd ed., 1901). On the interpretation of statutes, see Lord Farnborough, *The Machinery of Parliamentary Legislation* (1881); Sir C. P. Ilbert, *Legislative Methods and Forms* (1901); Sir H. Thring, *Practical Legislation, or the Composition and Language of Acts of Parliament* (1902).

Scotland.

The statutes of the Scottish parliament before the union differed from the English statutes in two important respects: they were passed by the estates of the kingdom sitting together and not in separate houses, and from 1367 to 1690 they were discussed only after preliminary consideration by the lords of the articles.[2] An act

[1] This opinion carries out to a certain extent the view of Locke, who in article 79 of his Carolina Code recommended the determination of acts of the legislature by effluxion of time after a hundred years from their enactment.

[2] The Scottish parliament from an early date discharged its functions by the aid of two committees known as the legislative and judicial committees. The legislative committee were termed lords of the articles and existed until 1688. The judicial committee were called lords auditors.

of the Scottish parliament may in certain cases cease to be binding by desuetude. "To bring an act of parliament like those we are dealing with" (*i.e.* the Sabbath Profanation Acts) "into what is called in Scots law the condition of desuetude, it must be shown that the offence prohibited is not only practised without being checked but is no longer considered or dealt with in this country as an offence against law" (Lord Justice General Inglis in *Bute's case*, 1 Couper's Rep., 495). Acts of the imperial parliament passed since the union extend in general to Scotland, unless that country be excluded from their operation by express terms or necessary implication. Scottish acts are cited thus, 1678, c. 10. The best edition is that issued by order of the Treasury, 1844–1875. An edition of the revised statutes has been facilitated by the repeal of obsolete statutes by the Statute Law Revision (Scotland) Act 1906.

Ireland.

Originally the lord deputy appears to have held parliaments at his option, and their acts were the only statutory law which applied to Ireland, except as far as judicial decisions had from motives of policy extended to that country the obligation of English statutes. In 1495 the act of the Irish parliament known as Poynings' Law or the Statute of Drogheda enacted that all statutes lately made in England be deemed good and effectual in Ireland. This was construed to mean that all statutes made in England prior to the 18 Hen. VII. were valid in Ireland, but none of later date were to have any operation unless Ireland were specially named therein or unless adopted by the Irish parliament (as was done, for instance, by Yelverton's Act, 21 & 22 Geo. III. c. 48 (I.). Another article of Poynings' Law secured an initiative of legislation to the English privy council, the Irish parliament having simply a power of acceptance or rejection of proposed legislation. The power of the parliament of Great Britain to make laws to bind the people of Ireland was declared by 6 Geo. I. c. 5. This act and the article of Poynings' Law were repealed in 1782, and the short-lived independence of the parliament of Ireland was recognized by 23 Geo. III. c. 28. The application of acts passed since the union is the same as in the case of Scotland. Divorce acts are still passed for Ireland (see DIVORCE). Irish acts are cited thus, 26 Geo. III. c. 15 (I.) or (Ir.). The best edition is that issued in twenty volumes pursuant to an order of the earl of Halifax, lord-lieutenant in 1762. A volume of revised statutes was published in 1885. The earliest that is still law is one of 1459.

British Colonies and Dependencies.

Acts of the imperial parliament do not extend to the Isle of Man, the Channel Islands or the colonies, unless they are specially named therein. By the Colonial Laws Validity Act 1865 ("the charter of colonial legislative independence") any colonial law repugnant to the provisions of any act of parliament extending to the colony is void to the extent of such repugnancy, and no colonial law is to be void by repugnancy to the law of England unless it be repugnant to such an act of parliament. For colonies without representative legislatures the Crown usually legislates, subject to the consent of parliament in particular cases. Examples of imperial legislation for the colonies in general are the Colonial Stock Act 1877, and the Colonial Courts of Admiralty Act 1890. For imperial acts dealing with particular colonies may be cited the British North America Act 1867, and the Commonwealth of Australia Constitution Act 1900. A colony is defined for the purposes of imperial legislation by the Interpretation Act 1889, s. 18. In many of the colonies, as in Canada, the constitutionality of an act of the colonial legislature is, as in the United States, a matter for the determination of the local court or of the judicial committee of the privy council on appeal.

United States.

By the constitutions of many states English statute law, as it existed at the time of the separation from England, and as far as it is applicable, has been adopted as part of the law of the states. The United States and the state are not bound by an act of Congress or a state law unless specially named. The states legislate for themselves within the limits of their own constitution and that of the United States. Here appears the striking difference between the binding force of a statute of the United Kingdom and an act passed by Congress or a state legislature. In the United Kingdom parliament is supreme; in the United States an act is only of authority if it is in accordance with the constitution. The courts may declare an act void if it contravene the constitution of the United States or of a state, so that practically the Supreme Court of the United States is the ultimate legislative authority. The restrictions upon Federal legislation in the constitution of the United States provide against the suspension of the writ of habeas corpus except in case of rebellion or invasion, the passing of a bill of attainder or *ex post facto* law, the imposition of capitation or other direct tax, unless in proportion to the several states, or of a tax or duty on exports, the preference of the ports of one state over those of another, the drawing of money from the treasury except by appropriations made by law, and the grant of a title of nobility. Constitutional amendments contain further limitations, *e.g.* the taking of private property for public use without just compensation, and the abridging of the right of citizens on account of race, colour or previous condition of servitude. State legislation is limited by s. 10: "No state shall . . . make anything but gold and silver coin a tender in payment of debts, pass any bill of attainder, *ex post facto* law, or law impairing the obligation of contracts, or grant any title of nobility." The section further forbids imposition of duties on imports or exports or any duty of tonnage without consent of Congress. State constitutions often contain further restrictions; among the more usual are provisions against laws with a retrospective operation, or impairing the obligation of contracts, or dealing with more than one subject to be expressed in the title. The time when a statute is to take effect after its passing is often fixed by state constitutions. The statutes of the United States were revised under the powers of an act of Congress passed in 1874 (sess. i. c. 333), and the volume of *Revised Statutes* was issued in 1875. There was a second edition in 1878 and several supplements have appeared since that date. Many of the states have also issued revised editions of their statutes. The rules of construction are in general agreement with those adopted in England. In some states the referendum has been introduced in certain cases.

Continental European Countries.

In most European countries there is a code, the existence of which makes the system of legislation hardly comparable to ours. The assent of two chambers and of the monarch, or president, is generally necessary. Greece is an exception; it is the only state in Europe with one chamber.

International Law.

The term "statute" is used by international jurists and civilians mostly on the continent of Europe to denote the whole body of the municipal law of the state. In this sense statutes are either real, personal or mixed. A real statute is that part of the law which deals directly with property, whether movable or immovable. A personal statute has for its object a person, and deals with questions of status, such as marriage, legitimacy or infancy. A mixed statute affects both property and person, or, according to some authorities, it deals with acts and obligations. Personal statutes are of universal validity; real statutes have no extra-territorial authority. The determination of the class under which a particular law ought to fall is one of great difficulty, and one in which there is often a conflict of legal opinion. On the whole the division appears to have created more difficulties than it has solved, and it is rejected by Savigny as unsatisfactory.

See Story, *Conflict of Laws*, §§ 12–16; Phillimore, *International Law*, vol. iv. ch. xvi.; Pillet, *Principes de droit international privé*, chs. xi. and xii. (J. W.)

STATUTE MERCHANT and **STATUTE STAPLE**, two old forms of security, long obsolete in English practice, though references to them still occur in some modern statutes. The former security was first created by the Statute of Acton Burnell (1283) and amplified by the Statute of Merchants (1285)—whence its name—and the latter by an act of 1353, which provided that in every staple (*i.e.* public mart) the seal of the staple should be sufficient validity for a bond of record acknowledged and witnessed before the mayor of the staple. They were originally permitted only among traders, for the benefit of commerce, but afterwards extended by an act of Henry VIII. (1532) to all subjects, whether traders or not. The creditor under either form of security was allowed to seize the goods and hold the lands of a defaulting debtor until satisfaction of his debt. While he held the lands he was termed tenant by statute merchant or by statute staple. In addition to the loss of his goods and lands the debtor was liable to be imprisoned. Statute merchant, owing to the summary method of enforcing payment, was sometimes known as "pocket judgment." Both were repealed by the Statute Law Revision Act 1863.

STAUNTON, SIR GEORGE THOMAS, BART. (1781–1859), English traveller and Orientalist, was born near Salisbury on the 26th of May 1781. He was the son of Sir George Leonard

Staunton (1737–1801), first baronet, diplomatist and Orientalist, and in 1792 accompanied his father, who had been appointed secretary to Lord Macartney's mission to China, to the Far East. He acquired a good knowledge of Chinese, and in 1798 was appointed a writer in the East India Company's factory at Canton, and subsequently its chief. In 1805 he translated a work of Dr George Pearson into Chinese, thereby introducing vaccination into China. In 1816 he proceeded as second commissioner on a special mission to Pekin with Lord Amherst and Sir Henry Ellis. Between 1818 and 1852 he was M.P. for several English constituencies, finally for Portsmouth. He was a member of the East India Committee, and in 1823, in conjunction with Henry Thomas Colebroke founded the Royal Asiatic Society. He died on the 10th of August 1859.

His publications include translations of *Ta Tsing leu lee, being the Fundamental Laws of China* (1810), the first Chinese book translated into English, and of the *Narrative of the Chinese Embassy to the Khan of the Tourgouth Tartars* (1821); *Miscellaneous Notices Relating to China and our Commercial Intercourse with that Country* (1822); *Notes of Proceedings and Occurrences during the British Embassy to Peking* (1824); *Observations on our Chinese Commerce* (1850). For the Hakluyt Society he edited Gonzalez de Mendoza's *History of the Great and Mighty Kingdom of China*.

STAUNTON, HOWARD (1810–1874), English Shakespearian scholar and writer on chess, supposed to have been a natural son of Frederic Howard, fifth earl of Carlisle, was born in 1810. He is said to have studied at Oxford, but if so, he never matriculated. Settling in London he soon spent the small fortune left him under his father's will and began to make his living by journalism. He gave much of his attention to the study of the English dramatists of the Elizabethan age. As a Shakespearian commentator he showed the qualities of acuteness and caution which made him excel in chess. He possessed, moreover, a thorough mastery of the literature of the period, shown in his papers in the *Athenaeum* on "Unsuspected Corruptions of Shakespeare's text," begun in October 1872. These formed part of the materials which he intended to utilize in a proposed edition of Shakespeare which never became an accomplished fact. In 1864 he published a facsimile of the Shakespeare folio of 1623, and a facsimile edition of *Much Ado about Nothing*, photolithographed from the quarto of 1600. He died in London on the 22nd of June 1874. Staunton's services to chess literature were very great, and the game in England owes much of its later popularity to him, while for thirty years he was the best player in England, perhaps in the world. For his important works on the subject see CHESS.

STAUNTON, an independent city and the county-seat of Augusta county, Virginia, U.S.A., about 135 m. N.W. of Richmond. Pop. (1890) 6975; (1900) 7289, including 1828 negroes and 149 foreign-born; (1910) 10,604. Staunton is served by the Chesapeake & Ohio and the Baltimore & Ohio railways. It lies between the Alleghany Mountains and the Blue Ridge, on a plateau about 1380 ft. above sea-level, in a fertile farming country with good pasture on the hillsides. In Staunton are a county court-house, the Western State hospital for the insane (1828), the Virginia school for the deaf and the blind (1839), the King's Daughters' hospital (1895), Dunsmore business college, Staunton military academy, the Mary Baldwin seminary, formerly Augusta female seminary (founded in 1842) and Stuart Hall (for girls), which was founded in 1843, was incorporated in 1845, and was reincorporated in 1907 under its present name in honour of Mrs J. E. B. Stuart, wife of the Confederate cavalry leader, who was its principal in 1879–1898. One mile east of Staunton is a U.S. national military cemetery with graves of 753 Union soldiers killed at Port Republic, Cross Keys and Piedmont; and west of the city is a Confederate cemetery with a memorial monument. The municipality owns the waterworks, the electric-lighting plant and the opera house An interesting feature of the city government is the employment of a business manager (elected annually by the city council), whose duties are in general similar to those of the business manager of a large corporation— *e.g.* he buys the city's supplies and has general supervision over the city improvements. The first settlement in this vicinity was on Lewis Creek, about 2 m. east of the city, in 1731. A county court-house was built here in 1745, and the name Staunton, in honour of the wife of Sir William Gooch (then lieutenant-governor), whose maiden name was Staunton, was used in 1748–1749, but Staunton was not incorporated as a town until 1761. It was chartered as a city in 1870, and then became a municipality independent of the county. The corporate limits of the city were extended in 1905 and, as its population thus became more than 10,000, Staunton was made a city of the first class.

STAUROLITE, a mineral consisting of basic aluminium and ferrous iron silicate with the formula $HFeAl_5Si_2O_{13}$. The material is, however, usually very impure, the crystals enclosing sometimes as much as 30 or 40% of quartz and other minerals as well as carbonaceous matter. Crystals are orthorhombic and have the form of six-sided prisms. Interpenetrating cruciform twinned crystals are very common and characteristic; they were early known as *pierres de croix* or *lapis crucifer*, and the name staurolite, given by J. C. Delamétherie in 1792, has the same meaning (Greek, σταυρός, a cross, and λίθος, a stone). In fig. 1 the twin-plane is (032) and the two prisms intercross

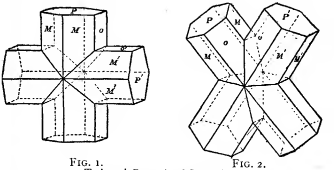

FIG. 1. FIG. 2.
Twinned Crystals of Staurolite.

at an angle of 91° 22′; in fig. 2 the twin-plane is (232) and the prisms intercross at nearly 60°. The mineral is translucent to opaque and dark reddish-brown in colour; it thus has a certain resemblance to garnet, and on this account has been called grenatite. Waterworn pebbles of material sufficiently transparent for cutting as gem-stones are occasionally found in the diamantiferous sands of Brazil. The hardness is 7½ and the specific gravity 3·75. Staurolite is a characteristic mineral of crystalline schists, and it is also a product of contact-metamorphism. Large twinned crystals with rough surfaces are found in mica-schist in Brittany and at several places in the United States, *e.g.* in Fannin county, Georgia. Untwinned crystals, translucent and of a rich brown colour (grenatite), are abundant in the silvery white paragonite-schist of Monte Campione, St Gothard. (L. J. S.)

STAVANGER, a seaport of Norway, capital of Stavanger *amt* (county), on the west coast in 59° N. (that of the Orkney Islands and northern Labrador). Pop. (1900), 30,541. It lies on the south side of the Bukken Fjord, and has a picturesque harbour well sheltered by islands. The town is one of the oldest in Norway, founded in the 8th or 9th century, but the present town is modern, though narrow, winding streets and wooden houses give it an antique appearance. It became the seat of a bishopric in the 13th century. Though the bishop's see was removed to Christiansand in 1685, the Romanesque cathedral church of St Swithun, founded by the English bishop Reinald in the end of the 11th century, and rebuilt after being burned down in 1272, remains, and, next to the cathedral of Trondhjem, is the most interesting stone church in Norway. There is an ornate painted pulpit of carved wood (1658). The old episcopal palace of Kongsgaard is now a Latin school. There are a theatre, an interesting museum of antiquities, natural history and art; and a picturesque park (Bjergsted). The industries of the town and its environs (Sandnaes, &c.) are prosperous, including factories for preserved foods, woollens and linens, lime, iodine from seaweed, and domestic commodities. The fisheries are important—for herring, mackerel, sprats, cod, salmon, lobsters and anchovies. On Rennes Island in the fjord, over against the town, there is a Cheviot sheep-breeding farm under government auspices. The imports consist principally of coal, salt, grain and flour, groceries, textiles, wood, and mineral oils. The most important export is fish, other items being seaweed, marble, preserved foods, butter and margarine and infusorial earth.

Stavanger is the first port of call for northward-bound passenger steamers from Hull and Newcastle, and has regular services from all the Norwegian coast towns, from Hamburg, &c. A railway runs south along the wild and desolate coast of Jaederen, one of the few low and unprotected shores in Norway, the scene of many wrecks. Stavanger commands a considerable tourist traffic. It is the starting-point of a favourite tour, embracing the fine valley of the Sand River, the great Lake Suldal and the Bratlandsdal. The Lyse Fjord, a branch of the Bukken Fjord, is a fine narrow inlet enclosed by precipitous mountains. Stavanger is the birthplace of Kjelland the novelist (1849).

STAVELEY, a town in the north-western parliamentary division of Derbyshire, England, 12 m. S.E. of Sheffield, on the Midland and the Great Central railways. Pop. (1901), 11,420. It lies in the valley of the Rother, in a populous industrial district, devoted chiefly to the working of coal and iron; while there are manufactures of iron goods and brushes in the town. The church of St John the Baptist is Early English, with much Perpendicular and modern alteration; it contains a number of interesting early monuments.

STAVELOT, an ancient town of Belgium, in the south-east of the province of Liége. Pop. (1904), 5037. Here Charles Martel gained a signal victory over Neustria in 719. A monastery had been established there half a century earlier by St Remacle, bishop of Tongres. The prince-abbot of Stavelot exercised secular authority over many towns in the Amblève and Warche valleys, including Malmédy (now in Prussia), and had a seat in the old German Diet. In 1815 the treaty of Vienna broke up the Stavelot principality, giving half to Prussia and half to the Netherlands. Only the tower of the old Benedictine abbey remains, and the shrine of St Remacle is preserved in the parish church.

STAVROPOL, a government of northern Caucasia, Russia, having an area of 26,492 sq. m. and bounded by the government of Astrakhan and the territory of the Don Cossacks on the N., by Kuban on the W. and by Terek on the S. and E. It occupies the eastern part of the broad steppes which stretch away north from the foot of the main chain of the Caucasus. The western part of the government is diversified by a broad undulating swelling, 1500 to 2000 ft. above sea-level; in the southern part of this swelling, and principally in Terek, there is a group of sixteen mountains, the Beshtau, 2800 to 4600 ft. in height, which are considered by H. Abich to be a porphyritic upheaval at the point of intersection of the two predominant orographical lines in the Caucasus (south-west to north-east and south-east to north-west). Northward and eastward of these heights are extensive steppes, 200 to 400 ft. above the sea, having gentle slopes both to the north (to the depression of the Manych) and to the east (towards the low, arid shores of the Caspian littoral).

Stavropol is chiefly drained by the Kuma and its tributaries (Karamyk and Buivola), its basin being the most fertile part of the government, but the evaporation is so great that the Kuma never reaches the Caspian except in spring. The Manych is not so much a river as a series of lakes, occupying a depression which formerly was a connecting channel between the Black Sea and the Caspian. This channel has two slopes, the eastern sometimes discharging its scanty water-supply into the Kuma, while on the western slope the elongated lakes which fill up the depression drain into the Don, reaching it however only during spring. Two Yegorlyks (Great and Middle), the Kalaus, and the Chogra (temporary tributaries of the Manych), drain the western part of Stavropol. On the whole, irrigation is restricted, and in the eastern steppes water is supplied only by cisterns. Besides the lakes of the Manych depression, there are many smaller salt lakes along the Caspian. Timber is scarce, even in the hilly tracts.

The climate is marked by rapid changes of temperature. The dry east winds are sometimes very violent in the spring and early summer, blowing the seeds out of the fields, and even destroying in a few days all existing vegetation. In July and August they continue for several weeks in succession, and choke the air with dust. The average temperatures at the town of Stavropol (altitude 2030 ft.) are much lower than one might expect in that latitude; that for the year is 47° Fahr., that for January 24°, and that for August 68°. The rainfall at the same place is 28·2 in., but other parts of the government are much worse off in this respect, the yearly rainfall being only 11 to 21½ in.

There is a great lack of forests, which are found only near the town of Stavropol and alongside of the main rivers. In the prairies the only arboreal vegetation is tamarisks and the dwarf almond tree. Altogether, except in the hilly parts of the government, the flora and fauna differ to a great extent from the flora and fauna of other parts of the Caucasus. Both resemble, on the one hand, those of Central Asia in such features as the presence, among mammals and birds, of the antelope *Saiga tatarica*, L., the steppe fox *Vulpes corsac*, Pallas, and the lark *Melanocorypha tatarica*, Pallas, and among plants of, firstly *Tamarix Pallasii*, *Statice caspia* and *Stipa lessingiana* (all characteristic of the arid prairies beyond the Urals), and secondly of species of *Salsola*, *Salicornia*, *Sueda*, *Artemisia*, *Kochia* and *Camphorosma*, all characteristic of the salt steppes of Asia; on the other hand, both flora and fauna have many features in common with the prairies of south Russia.

As regards geology, the whole of the government is covered with Tertiary and post-Tertiary deposits. Lower Miocene, Middle-Mediterranean deposits, and Sarmatian clays, limestones and sandstones crop out over nearly one-half of the surface of the government, namely, in its higher portion, while the remainder is buried under loess and fluviatile and lacustrine deposits. A narrow zone, now a low plain almost devoid of vegetation, is overlain with the so-called Caspian deposits.

The population is rapidly increasing, particularly from natural causes, and partly in consequence of immigration. In 1886 it was 702,635; in 1897, 879,758; and in 1906 was estimated at 1,023,700. The average density of the population is only 44 per sq. m., but in some districts it rises to 87. Russians form 90% of the population, the other races being Kalmucks, Turkomans, Nogai Tatars, Armenians, Georgians, Germans, Poles, &c. More than four-fifths of the population (81%) are Russian peasants. The nomad population occupies, however, more than one-third of the territory. There are four ordinary districts, the centres of administration in which are Stavropol, Alexandrovsk, Medvyezhinsk and Praskoveya, the chief town of the district of Novo-grigoryevsk; besides these the territory occupied by the nomads is divided into three districts, Bolshe-Derbetovskiy, Turkoman and Achikulak.

Agriculture is the most important occupation of the settled population, and so large is the harvest that no less than 16,000 labourers come annually from European Russia to assist in gathering in the crops. The peasants own some 48% of the total area, private persons 7%, the imperial government 2% and the Crown less than 2%. Agriculture is most successful on the wide prairie lands, where over 3,250,000 acres are annually under cereals. The principal crops are rye, wheat, oats, barley and potatoes. Melons, water-melons, flax and sunflowers are widely cultivated. Modern agricultural implements are in general use. Vineyards stretch for close upon 100 m. along the Kuma, and nearly 800,000 gallons of wine of an inferior quality are obtained annually. The factories are limited to flour-mills, oil-mills, distilleries, tanneries and candle works, and a few domestic industries are carried on in the villages. Considerable quantities of grain, flax, wool and hides are exported, and the fairs are very animated. Large amounts of corn are exported both to the mountainous districts of Caucasia and to Russia (Rostov-on-the-Don). Livestock breeding is engaged in very largely, not only by the Kalmucks, Turkomans and Nogai Tatars, but also by the Russians.

The northern slopes of the Caucasus began to be colonized by the Russians at a very early period, and as early as the 11th century part of the territory now occupied by Stavropol was known to Russian annalists as the Tmutarakan principality, which had Russian princes. A new attempt to colonize North Caucasia was made in the 16th century, under Ivan the Terrible, who married a Kabardian princess. This was again unsuccessful, and it was not till 1711 that Russia began regularly to colonize the territory by Cossack settlements. Kizlyar was founded in 1736, Stavropol in 1776 or 1777. Vast tracts of lands were given by Catherine II. to her courtiers, who began to people them with serfs from Russia.

(P. A. K.; J. T. Be.)

STAVROPOL, a town of southern Russia, capital of the government of the same name, situated on a plateau 2030 ft. above the sea, on the northern slope of the Caucasus, 200 m. N.W. of Vladikavkaz. It is connected by rail (247 m.) with Rostov-on-the-Don. Although founded only in 1776, it has grown rapidly, and had in 1885 a population of 35,561, and of 46,965 in 1900. Stavropol is an episcopal see of the Orthodox Greek Church, and one of the best-built provincial towns of the

Russian Empire, having wide streets, and houses mostly of stone, with large gardens surrounding the houses. There are public libraries, a people's palace and several scientific societies. Stavropol has flour-mills and various small factories. Large numbers of cattle are sent to Moscow and St Petersburg, while cereals, tallow and sheepskins are exported to Russia, and manufactured wares imported. Armenian, Georgian and Persian merchants carry on a lively trade in local wares.

STAWELL, SIR WILLIAM FOSTER (1815–1889), British colonial statesman, was the son of Jonas Stawell, of Old Court, in the county of Cork, and of Anna, daughter of the Right Rev. William Foster, bishop of Clogher. He was born on the 27th of June 1815, was educated at Trinity College, Dublin, studied law at King's Inn, Dublin, and Lincoln's Inn, and was called to the Irish bar in 1839. He practised in Ireland until 1842, and then, making his home in Australia, was admitted to the Melbourne bar in 1843. He engaged extensively in pastoral pursuits, and had sheep stations at Natte Yallock, on the banks of the river Avoca, and in the neighbourhood of Lake Wallace, near the South Australian border. For many years he enjoyed the leading practice at the local bar, and when the Port Phillip district of New South Wales was separated from the parent colony, and entered upon an independent existence as the colony of Victoria, Mr Stawell accepted the position of attorney-general and became a member of the executive and legislative councils. A few weeks after his appointment gold was discovered, and to Mr Stawell fell the arduous duties of creating a system of government which could cope adequately with the difficulties of the position. He had to establish a police force, frame regulations for the government of the goldfields, appoint magistrates and officials of every grade, and protect life and property against the attacks of the hordes of adventurers, many of desperate character, who landed in Victoria, first from the neighbouring colonies, and later from Europe and America. It was very much owing to the firm administration of Mr Stawell that, at a time when the government was weak and a large section of the newcomers impatient of control, lynch law was never resorted to. He had very little assistance for some time from any of his colleagues, and until the executive council was strengthened by the admission of Captain (afterwards Sir Andrew) Clarke and Mr H. C. E. Childers Mr Stawell was the brains as well as the body of the administration. The success of his policy was upon the whole remarkable. In the legislature he was sometimes opposed, and at other times assisted, by Mr (afterwards Sir John) O'Shanassy, who was the leader of the popular party, and between them they managed to pass a number of statutes which added greatly to the prosperity of the colony. Mr Stawell was indefatigable in the discharge of his duties, and extraordinary stories are told of the long journeys on horseback to visit distant outposts which he would take after being all day long in the law courts or in the council chamber. Mr Stawell bore an active part in drafting the Constitution Act which gave to Victoria representative institutions and a responsible ministry, instead of an executive appointed and removable by the governor and a legislature in which one-third of the members were chosen by the Crown. At the first general election after the new constitution in 1856 Mr Stawell was returned as one of the members for Melbourne, and became the attorney-general of the first responsible ministry. In 1857, on the resignation of the chief justice, Sir William A'Beckett, he succeeded to the vacant post, and was created a knight-bachelor. He administered the government of Victoria in 1873, 1875–1876, and 1884. Sir William never left Australia from his arrival in 1843 till 1872, when he paid short visits to the neighbouring colonies and New Zealand, and 1873, when he returned to Europe on two years' leave of absence. He took a very deep interest in the proceedings of the Church of England, and was a member of the synod. On his retirement from the bench in 1886 he was created K.C.M.G. He died at Naples in 1889. In 1856 he had married Mary Frances Elizabeth, only daughter of W. P. Greene, R.N. (G. C. L.)

STAWELL, a municipality of Borung county, Victoria, Australia, 179 m. by rail W.N.W. of Melbourne. Pop. (1901), 5296. The quartz reefs of the Pleasant Creek goldfields near the town are worked at very deep levels and there are several extensive cyanide plants on the reef. In the adjacent Grampians, which are connected by rail with Stawell, there are numerous freestone quarries. Wheat is extensively grown in the vicinity and also large numbers of vines, for which the soil is particularly adapted. Stawell is the changing station on the line from Melbourne to Adelaide, and has large engine-houses and repairing shops.

STAY BARS, in architecture, saddle bars passing through the mullions in one length across the whole window, and secured to the jambs on each side (see SADDLE).

STEAD, WILLIAM THOMAS (1849–), English journalist, was born at Embleton, Northumberland, on the 5th of July 1849, the son of a Congregational minister. He went to school at Wakefield, but was early apprenticed in a merchant's office at Newcastle-on-Tyne; he soon gravitated however, into journalism, and in 1871 became editor of the Darlington *Northern Echo*. In 1880 he went to London to be assistant editor of the *Pall Mall Gazette* under John Morley, and when the latter retired he became editor (1883–1889). Up to 1885 he had distinguished himself for his vigorous handling of public affairs, and his brilliant modernity in the presentation of news. He introduced the "interview," made a feature of the *Pall Mall* "extras" (see also NEWSPAPERS: *London*), and his enterprise and originality exercised a potent influence on contemporary journalism and politics. His enthusiasm, however, carried him too far when in 1885 he entered upon a crusade against vice by publishing a series of articles on the "Maiden Tribute of Modern Babylon." Though his action undoubtedly furthered the passing of the Criminal Law Amendment Act, it made his position on the paper impossible; and his imprisonment at Holloway for three months on a charge arising out of his crusade made his connexion with the whole subject a source of considerable prejudice. On leaving the *Pall Mall* he founded the monthly *Review of Reviews* (1890), and his abundant energy and facile pen found scope in many other directions in journalism of an advanced humanitarian type. He started cheap reprints (*Penny Poets* and *Prose Classics*, &c.), conducted a spiritualistic organ, called *Borderland* (1893–1897), in which he gave full play to his interest in psychical research; and became an enthusiastic supporter of the peace movement, and of many other movements, popular and unpopular, in which he impressed the public generally as an extreme visionary, though his practical energy was recognized by a considerable circle of admirers and pupils. At the time of the Boer War of 1899 he threw himself into the Boer cause and attacked the government with characteristic violence. Yet amid all his unpopularity, and all the suspicion and opposition engendered by his methods, his personality remained a forceful one both in public and private life. He was an early imperialist dreamer, whose influence on Cecil Rhodes in South Africa remained of primary importance; and many politicians and statesmen, who on most subjects were completely at variance with his ideas, nevertheless owed something to them. Mr Rhodes made him his confidant, and was inspired in his will by his suggestions; and Mr Stead was intended to be one of Mr Rhodes's executors, though his name was struck out after the Boer War (see his *Last Will and Testament of C. J. Rhodes*, 1902). The number of his publications gradually became very large, as he wrote with facility and sensational fervour on all sorts of subjects, from *The Truth about Russia* (1888) to *If Christ came to Chicago* (1893), and from *Mrs Booth* (1900) to *The Americanization of the World* (1902). In private life his keen sense of merit and kindly interest influenced many aspirants to journalism and literature.

STEAK, a thick slice or piece of meat cut for frying, broiling or stewing. The word is apparently derived from Icel. *steik*, used in the same sense, which meant properly roasted meat, from *steikja*, to roast, that is, placed on a stick or peg of wood before the fire, *stika*, stick, cf. Swed. *stek*; Dan. *steg*, roast meat. A steak may be cut from any meat or fish, hut the best-known is a "beef-steak," cut properly from the rump a "rump-steak," or part of the loin a "tenderloin." A "porter-house" steak is a choice cut of steak from the loin, so named apparently first in New York from a well-known "porter-house," an eating-house where chops, steaks, &c., and porter or stout were served, at which these steaks were a speciality. A steak grilled between two other steaks, which are not served after the cooking is finished, is also sometimes called a "porter-house" steak.

STEAM (O. Eng. *steam*, vapour, smoke, cf. Du. *stoom*; the origin is unknown), water-vapour. Dry steam is steam free from mechanically mixed water particles; wet steam, on the other hand, contains water particles in suspension. Saturated steam is steam in contact with liquid water at a temperature which is the boiling point of the water and condensing point of the steam; superheated steam is steam out of contact with water heated above this temperature. For theoretical considerations see VAPORIZATION, and for the most important application see STEAM ENGINE; also WATER.

STEAM ENGINE. 1. A steam engine is a machine for the conversion of heat into mechanical work, in which the working substance is water and water vapour. The working substance may be regarded from two points of view. Thermodynamically it is the vehicle by which heat is conveyed to and through the engine from the hot source (the furnace and boiler). Part of this heat suffers a transformation into work as it passes through, and the remainder is rejected, still in the form of heat. Mechanically the working substance is a medium capable of exerting pressure, which effects this transformation in doing work by means of the changes of volume which it undergoes in the operation of the machine. Regarded as a thermodynamic device, the function of the engine is to get as much work as possible from a given quantity of heat or, to go a step further back, from the combustion of a given quantity of fuel. Accordingly, a question of primary importance is what is called the *efficiency* of the engine, which is the ratio of the work done to the heat supplied. Before, however, proceeding to discuss the steam engine in this aspect, or treating of the mechanics of its modern forms, it may be useful to give a brief historical sketch of its early development as an industrial appliance. In any such sketch the chief share of attention must necessarily be given to the work of James Watt. But a process of evolution had been going on before the time of Watt which prepared the steam engine for the immense improvements it received at his hands. His labours stand in natural sequence to those of Thomas Newcomen, and Newcomen's to those of Denis Papin and Thomas Savery. Savery's engine in its turn was the reduction to practical form of a contrivance which had long before heen known as a scientific toy. The most modern type of all, the steam turbine of C. A. Parsons, is a new departure which has but little to connect it directly with the past; but even the steam turbine not only profits by the inventions of Watt, but in its characteristic feature finds crude prototypes in apparatus which employed the kinetic energy of jets of steam.

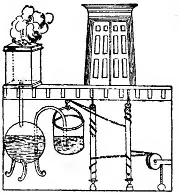

FIG. 1.—Hero's Apparatus, 130 B.C.

Hero, 130 B.C.

2. One of these, indeed, is mentioned amongst the earliest notices we have of any heat engine. In the *Pneumatica* of Hero of Alexandria (*c.* 130 B.C.) there is described the aeolipile, which is a primitive steam reaction turbine, consisting of a spherical vessel pivoted on a central axis and supplied with steam through one of the pivots. The steam escapes by bent pipes facing tangentially in opposite directions, at opposite ends of a diameter perpendicular to the axis. The globe revolves by reaction from the escaping steam just as a Barker's mill is driven by escaping water. Another apparatus described by Hero (fig. 1)[1] is interesting as the prototype of a class of engines which long afterwards became practically important. A hollow altar containing air is heated by a fire kindled on it; the air in expanding drives some of the water contained in a spherical vessel beneath the altar into a bucket, which descends and opens the temple doors above by pulling round a pair of vertical posts to which the doors are fixed. When the fire is extinguished the air cools, the water leaves the bucket, and the doors close. In another device a jet of water driven out by expanding air is turned to account as a fountain.

Della Porta, 1601.

3. From the time of Hero to the 17th century there is no progress to record, though here and there we find evidence that appliances like those described by Hero were used for trivial purposes, such as organ-blowing and the turning of spits. The next distinct step was the publication in 1601 of a treatise on pneumatics by Giovanni Battista della Porta, in which he shows an apparatus similar to Hero's fountain, but with steam instead of air as the displacing fluid. Steam generated in a separate vessel passes into a closed chamber containing water, from which a pipe (open under the water) leads out. He also points out that the condensation of steam in the closed chamber may be used to produce a vacuum and suck up water from a lower level. In fact, his suggestions anticipate very fully the engine which a century later became in the hands of Savery the earliest commercially successful steam engine. In 1615 Solomon de Caus gives a plan of forcing up water by a steam fountain which differs from Della Porta's only in having one vessel serve both as boiler and as displacement-chamber, the hot water being itself raised.

4. Another line of invention was taken by Giovanni Branca (1629), who designed an engine shaped like a water-wheel, to be driven by the impact of a jet of steam on its vanes, and in its turn to drive other mechanism for various useful purposes. But Branca's suggestion was for the time unproductive, and we find the course of invention reverting to the line followed by Della Porta and De Caus.

Marquis of Worcester, 1663.

5. The next contributor is one whose place is not easily assigned. To Edward Somerset, second marquis of Worcester, appears to be due the credit of proposing, if not making, the first useful steam engine. Its object was to raise water, and it worked probably like Della Porta's model, but with a pair of displacement-chambers, from each of which alternately water was forced by steam from an independent boiler, or perhaps by applying heat to the chamber itself, while the other vessel was allowed to refill. Lord Worcester's description of the engine in art. 68 of his *Century of Inventions* (1663) is obscure, and no drawings are extant. It is, therefore, difficult to say whether there were any distinctly novel features except the double action; in particular, it is not clear whether the suction of a vacuum was used to raise water as well as the direct pressure of steam.

Savery, 1698.

6. The steam engine first became commercially successful in the hands of Thomas Savery,[2] who, in 1698, obtained a patent for a water-raising engine, shown in fig. 2. Steam is admitted to one of the oval vessels A, displacing water, which it drives up through the check-valve B. When the vessel A is emptied of water the supply of steam is stopped, and the steam already there is condensed by allowing a jet of cold water from a cistern above to stream over the outer surface of the vessel. This produces a vacuum and causes water to be sucked up through the pipe C and the valve D. Meanwhile steam has been displacing water

[1] From Greenwood's translation of Hero's *Pneumatica*.

[2] Savery was born probably in 1650 and died in 1715. See Sir E. Durning Lawrence's presidential address to the Royal Institution of Cornwall (*Journ. of the Roy. Inst. of Cornwall*, No. li.), republished with a reprint of Savery's *Miner's Friend* of 1702, in which he discusses the originality of Savery's invention and dismisses the claims put forward for Lord Worcester.

from the other vessel, and is ready to be condensed there. The valves B and D open only upwards. The supplementary boiler and furnace E are for feeding water to the main boiler; E is filled while cold and a fire is lighted under it; it then acts like the vessel of De Gaus in forcing a supply of feed-water into the main boiler F. The gauge cocks G, G are an interesting feature in detail. Another form of Savery's engine had only one displacement-chamber and worked intermittently. In the use of artificial means to condense the steam, and in the application of the vacuum so formed to raise water by suction from a level lower than that of the engine, Savery's engine was probably an improvement on Worcester's; in any case it found what Worcester's engine had failed to find—considerable employment in pumping mines and in raising water to supply houses and towns, and even to drive water-wheels. A serious difficulty which prevented its general use in mines was the fact that the height through which it would lift water was limited by the pressure the boiler and vessels could bear. Pressures as high as 8 or 10 atmospheres were employed—and that, too, without a safety-valve—but Savery found it no easy matter to deal with high-pressure steam; he complains that it melted his common solder, and forced him, as Desaguliers tells us, " to be at the pains and charge to have all his joints soldered with spelter." Apart from this drawback, the waste of fuel was enormous, from the condensation of steam which took place on the surface of the water and on the sides of the displacement-chamber at each stroke; the consumption of coal was, in proportion to the work done, some twenty times greater than in a good modern steam engine. In a tract called *The Miner's Friend* Savery alludes thus to the alternate heating and cooling of the water-vessel: " On the outside of the vessel you may see how the water goes out as well as if the vessel were transparent, for so far as the steam continues within the vessel so far is the vessel dry without and so very hot as scarce to endure the least touch of the hand. But as far as the water is, the said vessel will be cold and wet where any water has fallen on it; which cold and moisture vanishes as fast as the steam in its descent takes the place of the water." Before Savery's engine was entirely displaced by its successor, Newcomen's, it was improved by J. T. Desaguliers, who applied to it the safety valve (invented by Papin), and substituted condensation by a jet of cold water within the vessel for the surface condensation used by Savery. To Savery is ascribed the first use of the term " horse power " as a measure of the performance of an engine.

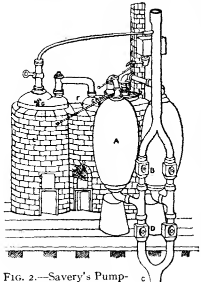

FIG. 2.—Savery's Pumping Engine, 1698.

Cylinder and Piston Engine.

7. So early as 1678 the use of a piston and cylinder (long before known as applied to pumps) in a heat-engine had been suggested by Jean de Hautefeuille, who proposed to use the explosion of gun-powder either to raise a piston or to force up water, or to produce, by the subsequent cooling of the gases, a partial vacuum into which water might be sucked up. Two years later Christian Huygens described an engine in which the explosion of gun-powder in a cylinder expelled part of the gaseous contents, after which the cooling of the remainder caused a piston to descend under atmospheric pressure, and the piston in descending did work by raising a weight.

Papin.

8. In 1690 Denis Papin, who ten years before had invented the safety-valve as an adjunct to his " digester," suggested that the condensation of steam should be employed to make a vacuum under a piston previously raised by the expansion of the steam. Papin's was the earliest cylinder and piston steam engine, and his plan of using steam was that which afterwards took practical shape in the atmospheric engine of Newcomen. But his scheme was made unworkable by the fact that he proposed to use but one vessel as both boiler and cylinder. A small quantity of water was placed at the bottom of a cylinder and heat was applied. When the piston had risen the fire was removed, the steam was allowed to cool, and the piston did work in its down-stroke under the pressure of the atmosphere. After hearing of Savery's engine in 1705 Papin turned his attention to improving it, and devised a modified form, shown in fig. 3, in which the displacement-chamber A was a cylinder, with a floating diaphragm or piston on the top of the water to keep the water and steam from direct contact with one another. The water was delivered into a closed air-vessel B, from which it issued in a continuous stream, against the vanes of a water-wheel. After the steam had done its work in the displacement-chamber it was allowed to escape by the stop-cock C instead of being condensed. Papin's engine was, in fact, a non-condensing single-acting steam pump, with steam cylinder and pump cylinder in one. A curious feature of it was the heater D, a hot mass of metal placed in the diaphragm for the purpose of keeping the steam dry. Among the many inventions of Papin was a boiler with an internal fire-box—the earliest example of a construction that is now almost universal.[1]

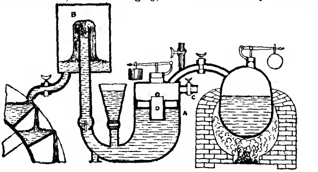

FIG. 3.—Papin, 1705.

Newcomen's Atmospheric Engine, 1705.

9. While Papin was thus going back from his first notion of a piston engine to Savery's cruder type, a new inventor had appeared who made the piston engine a practical success by separating the boiler from the cylinder and by using (as Savery had done) artificial means to condense the steam. This was Thomas Newcomen, who in 1705, with his assistant, John Cawley, gave the steam engine the form shown in fig. 4. Steam admitted from the boiler to the cylinder allowed the piston to be raised by a heavy counterpoise on the other side of the beam. Then the steam valve was shut and a jet of cold water entered the cylinder and condensed the steam. The piston was consequently forced down by the pressure of the atmosphere and did work on the pump. The next entry of steam expelled the condensed water from the cylinder

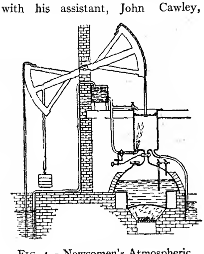

FIG. 4.—Newcomen's Atmospheric Engine, 1705.

[1] For an account of Papin's inventions see his *Life and Correspondence*, by Dr E. Gerland (Berlin, 1881).

through an escape valve. The piston was kept tight by a layer of water on its upper surface. Condensation was at first effected by cooling the outside of the cylinder, but the accidental leakage of the packing water past the piston showed the advantage of condensing by a jet of injection water, and this plan took the place of surface condensation. The engine used steam whose pressure was little if at all greater than that of the atmosphere; sometimes, indeed, it was worked with the manhole lid off the boiler.

Self-acting Valve-gear.

10. About 1711 Newcomen's engine began to be introduced for pumping mines. It is doubtful whether the action was originally automatic, or depended on the periodical turning of taps by an attendant. The common story is that in 1713 a boy named Humphrey Potter, whose duty it was to open and shut the valves of an engine he attended, made the engine self-acting by causing the beam itself to open and close the valves by suitable cords and catches. This device was simplified in 1718 by Henry Beighton, who suspended from the beam a rod called the plug-tree, which worked the valves by means of tappets. By 1725 the engine was in common use in collieries, and it held its place without material change for about three-quarters of a century in all. Near the close of its career the atmospheric engine was much improved in its mechanical details by John Smeaton, who built many large engines of this type about the year 1770, just after the great step which was to make Newcomen's engine obsolete had been taken by James Watt.

Compared with Savery's engine, Newcomen's had (as a pumping engine) the great advantage that the intensity of pressure in the pumps was not in any way limited by the pressure of the steam. It shared with Savery's, in a scarcely less degree, the defect already pointed out, that steam was wasted by the alternate heating and cooling of the vessel into which it was led. Though obviously capable of more extended uses, it was in fact almost exclusively employed to raise water—in some instances for the purpose of turning water-wheels to drive other machinery. Even contemporary writers complain of its vast "consumption of fuel," which appears to have been scarcely smaller than that of the engine of Savery.

Watt, 1763.

11. In 1763 James Watt, an instrument maker in Glasgow, while engaged by the university in repairing a model of Newcomen's engine, was struck with the waste of steam to which the alternate chilling and heating of the cylinder gave rise. He saw that the remedy, in his own words, would lie in keeping the cylinder as hot as the steam that entered it. With this view he added to the engine a new organ—an empty vessel separate from the cylinder, into which the steam should be allowed to escape from the cylinder, to be condensed there by the application of cold water either outside or as a jet. To preserve the vacuum in his condenser he added a pump called the air-pump, whose function was to pump from it the condensed steam and water of condensation, as well as the air which would otherwise accumulate by leakage or by being brought in with the steam or with the injection water. Then, as the cylinder was no longer used as a condenser, he was able to keep it hot by clothing it with non-conducting bodies, and in particular by the use of a *steam jacket*, or layer of hot steam between the cylinder and an external casing. Further, and still with the same object, he covered in the top of the cylinder, taking the piston-rod out through a steam-tight stuffing-box, and allowed steam instead of air to press upon the piston's upper surface. The idea of using a separate condenser had no sooner occurred to Watt than he put it to the test by constructing the apparatus shown in fig. 5. There A is the cylinder, B a surface condenser, and C the air-pump. The cylinder was filled with steam above the piston, and a vacuum was formed in the surface condenser B.

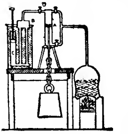

Fig. 5.—Watt's Experimental Apparatus.

On opening the stop-cock D the steam rushed over from the cylinder and was condensed, while the piston rose and lifted a weight. After several trials Watt patented his improvements in 1769; they are described in his specification in the following words, which, apart from their immense historical interest, deserve careful study as a statement of principles which to this day guide the scientific development of the steam engine:—

"My method of lessening the consumption of steam, and consequently fuel, in fire-engines, consists of the following principles:—

"*First*, That vessel in which the powers of steam are to be employed to work the engine, which is called the cylinder in common fire-engines, and which I call the steam-vessel, must, during the whole time the engine is at work, be kept as hot as the steam that enters it; first by enclosing it in a case of wood, or any other materials that transmit heat slowly; secondly, by surrounding it with steam or other heated bodies; and, thirdly, by suffering neither water nor any other substance colder than the steam to enter or touch it during that time.

"*Secondly*, In engines that are to be worked wholly or partially by condensation of steam, the steam is to be condensed in vessels distinct from the steam-vessels or cylinders, although occasionally communicating with them; these vessels I call condensers; and, whilst the engines are working, these condensers ought at least to be kept as cold as the air in the neighbourhood of the engines, by application of water or other cold bodies.

"*Thirdly*, Whatever air or other elastic vapour is not condensed by the cold of the condenser, and may impede the working of the engine, is to be drawn out of the steam-vessels or condensers by means of pumps, wrought by the engines themselves, or otherwise.

"*Fourthly*, I intend in many cases to employ the expansive force of steam to press on the pistons, or whatever may be used instead of them, in the same manner in which the pressure of the atmosphere is now employed in common fire-engines. In cases where cold water cannot be had in plenty, the engines may be wrought by this force of steam only, by discharging the steam into the air after it has done its office. . . .

"*Sixthly*, I intend in some cases to apply a degree of cold not capable of reducing the steam to water, but of contracting it considerably, so that the engines shall be worked by the alternate expansion and contraction of the steam.

"*Lastly*, Instead of using water to render the pistons and other parts of the engine air and steam tight, I employ oils, wax, resinous bodies, fat of animals, quicksilver and other metals in their fluid state."

The fifth claim was for a rotary engine, and need not be quoted here.

The "common fire engine" alluded to was the steam engine, or, as it was more generally called, the "atmospheric" engine of Newcomen. Enormously important as Watt's first patent was, it resulted for a time in the production of nothing more than a greatly improved engine of the Newcomen type, much less wasteful of fuel, able to make faster strokes, but still only suitable for pumping, still single-acting, with steam admitted during the whole stroke, the piston, as before, pulling the beam by a chain working on a circular arc. The condenser was generally worked by injection, but Watt has left a model of a surface condenser made up of small tubes, in every essential respect like the condensers now used in marine engines.[1]

Watt's Pumping Engine, 1769.

12. Fig. 6 is an example of the Watt pumping engine of this period. It should be noticed that, although the top of the cylinder is closed and steam has access to the upper side of the piston, this is done only to keep the cylinder and piston warm. The engine is still single-acting; the steam in the upper side merely plays the part which was played in Newcomen's engine by the atmosphere; and it is the lower end of the cylinder alone that is ever put in communication with the condenser. There are three valves: the "steam" valve *a*, the "equilibrium" valve *b*, and the "exhaust" valve *c*. At the beginning of the down-stroke *c* is opened to produce a vacuum below the piston and *a* is opened to admit steam above it. At the end of the down-stroke *a* and *c* are shut and *b* is opened. This puts the two sides in equilibrium and allows the piston to be pulled up by the pump-rod *P*, which is heavy enough to serve as a counterpoise. *C* is the condenser, and *A* the air-pump, which discharges into the hot well *H*, whence the supply of the feed-pump *F* is drawn.

13. In a second patent (1781) Watt describes the "sun-and-planet" wheels and other methods of making the engine give

[1] An interesting detailed narrative of the steps leading to his invention was written by Watt as a note to the article "Steam Engine" in Robison's *System of Mechanical Philosophy* (1822). See Ewing, *The Steam Engine and other Heat Engines*, pp. 15–19.

continuous revolving motion to a shaft provided with a flywheel. He had invented the crank and connecting-rod for this purpose, but it had meanwhile been patented by one Pickard, and Watt, rather than make terms with Pickard, whom he regarded as a plagiarist of his own ideas, made use of his sun-and-planet motion until the patent on the crank expired. The reciprocating motion of earlier forms had served only for pumping; by this invention Watt opened up for the steam engine a thousand other channels of

Rotative Engine.

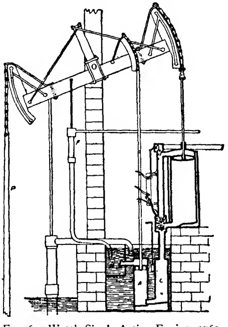

FIG. 6.—Watt's Single-Acting Engine, 1769.

usefulness. The engine was still single-acting; the connecting-rod was attached to the far end of the beam, and that carried a counterpoise which served to raise the piston when steam was admitted below it.

14. In 1782 Watt patented two further improvements of the first importance, both of which he had invented some years before. One was the use of double action, that is to say, the application of steam and vacuum to each side of the piston alternately. The other (invented as early as 1769) was the use of steam expansively, in other words the plan (now used in all engines that aim at economy of fuel) of stopping the admission of steam when the piston had made only a part of its stroke, and allowing the rest of the stroke to be performed by the expansion of the steam already in the cylinder. To let the piston push as well as pull the end of the beam Watt devised his so-called parallel motion, an arrangement of links connecting the piston-rod head with the beam in such a way as to guide the rod to move in a very nearly straight line. He further added the throttle valve, for regulating the rate of admission of steam, and the centrifugal governor, a double conical pendulum, which controlled the speed by acting on the throttle-valve. The stage of development reached at this time is illustrated by the engine of fig. 7 (from Stuart's *History of the Steam Engine*), which shows the parallel motion *pp*, the governor *g*, the throttle-valve *t*, and a pair of steam and exhaust valves at each end of the cylinder. Among other inventions of Watt were the "indicator," by which diagrams showing the relation of the steam pressure in the cylinder to the movement of the piston are automatically drawn; a steam tilt-hammer; and also a steam locomotive for ordinary roads—but this invention was not prosecuted.

Other inventions of Watt.

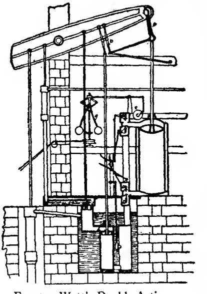

FIG. 7.—Watt's Double-Acting Engine, 1782.

In partnership with Matthew Boulton, Watt carried on in Birmingham the manufacture and sale of his engines with the utmost success, and held the field against all rivals in spite of severe assaults on the validity of his patents. Notwithstanding his accurate knowledge of the advantage to be gained by using steam expansively, he continued to employ only low pressures—seldom more than 7 lb per sq. in. over that of the atmosphere. His boilers were fed, as Newcomen's had been, through an open pipe which rose high enough to let the column of water in it balance the pressure of the steam. He gave a definite numerical significance to the term "horse-power" (*q.v.*) as a mode of rating engines, defining it as the rate at which work is done when 33,000 lb are raised one foot in one minute.

15. In the fourth claim in Watt's first patent the second sentence describes a non-condensing engine, which would have required steam of a higher pressure. This, however, was a line of invention which Watt did not follow up, perhaps because so early as 1725 a non-condensing engine had been described by Jacob Leupold in his *Theatrum machinarum*. Leupold's proposed engine is shown in fig. 8, which makes its action sufficiently clear. Watt's aversion to high-pressure steam was strong, and its influence on steam engine practice long survived the expiry of his patents. So much indeed was this the case that the terms "high-pressure" and "non-condensing" were for many years synonymous in contradistinction to the "low-pressure" or condensing engines of Watt. This nomenclature no longer holds; in modern practice many condensing engines use as high pressures as non-condensing engines, and by doing so are able to take advantage of Watt's great invention of expansive working to a degree which was impossible in his own practice.

Non-condensing Engine.

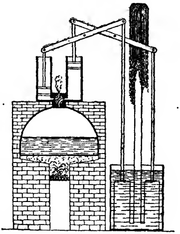

FIG. 8.—Leupold's Non-Condensing Engine, 1725.

16. The introduction of the non-condensing and, at that time, relatively high-pressure engine was effected in England by Richard Trevithick and in America by Oliver Evans about 1800. Both Evans and Trevithick applied their engines to propel carriages on roads, and both used for boiler a cylindrical vessel with a cylindrical flue inside—the construction now known as the Cornish boiler. In partnership with William Bull, Trevithick had previously made direct acting pumping-engines, with an inverted cylinder set over and in line with the pump-rod, thus dispensing with the beam that had been a feature in all earlier forms. But in these "Bull" engines, as they were called, a condenser was used, or, rather, the steam was condensed by a jet of cold water in the exhaust-pipe, and Boulton and Watt successfully opposed them as infringing Watt's patents. To Trevithick belongs the distinguished honour of being the first to use a steam carriage on a railway; in 1804 he built a locomotive in the modern sense, to run on what had formerly been a horse-tramway, in Wales, and it is noteworthy that the

High-pressure Steam.

exhaust steam was discharged into the funnel to force the furnace draught, a device which, twenty-five years later, in the hands of George Stephenson, went far to make the locomotive what it is to-day. In this connexion it may be added that as early as 1769 a steam carriage for roads had been built in France by Nicolas Joseph Cugnot, who used a pair of single-acting high-pressure cylinders to turn a driving axle step by step by means of pawls and ratchet-wheels. To the initiative of Evans may be ascribed the early general use of high-pressure steam in the United States, a feature which for many years distinguished American from English practice.

17. Amongst the contemporaries of Watt one name deserves special mention. In 1781 Jonathan Carter Hornblower constructed and patented what would now be called a compound engine, with two cylinders of different sizes. Steam was first admitted into the smaller cylinder, and then passed over into the larger, doing work against a piston in each. In Hornblower's engine the two cylinders were placed side by side, and both pistons worked on the same end of a beam overhead. This was an instance of the use of steam expansively, and as such was earlier than the patent, though not earlier than the invention, of expansive working by Watt. Hornblower was crushed by the Birmingham firm for infringing their patent in the use of a separate condenser and air-pump. The compound engine was revived in 1804 by Arthur Woolf, with whose name it is often associated. Using steam of fairly high pressure, and cutting off the supply before the end of the stroke in the small cylinder, Woolf expanded the steam to several times its original volume. Mechanically the double-cylinder compound engine has this advantage over an engine in which the same amount of expansion is performed in a single cylinder, that the sum of the forces exerted by the two pistons in the compound engine varies less throughout the action than the force exerted by the piston of the single-cylinder engine. This advantage may have been clear to Hornblower and Woolf and to other early users of compound expansion. But another and probably a more important merit of the system lies in a fact of which neither they nor for many years their followers in the use of compound engines were aware —the fact that by dividing the whole range of expansion into two parts the cylinders in which these are separately performed are subject to a reduced range of fluctuation in their temperature. This, as will be seen later, limits to a great extent a source of waste which is present in all steam engines, the waste which results from the heating and cooling of the metal by its alternate contact with hot and cooler steam. The system of compound expansion is now used in nearly all large engines that pretend to economy. Its introduction forms the most outstanding improvement which steam engines of the piston and cylinder type have undergone since the time of Watt; and we are able to recognize it as a very important step in the direction set forth in his "first principle" that the cylinder should be kept as hot as the steam that enters it.

Compound Engine.

18. Woolf introduced the compound engine somewhat widely about 1814 as a pumping engine in the mines of Cornwall. But here it met a strong competitor in the high-pressure single-cylinder engine of Trevithick, which had the advantage of greater simplicity in construction. Woolf's engine fell into comparative disuse, and the single-cylinder type took a form which, under the name of the Cornish pumping engine, was for many years famous for its great economy of fuel. In this engine the cylinder was set under one end of a beam, from the other end of which hung a heavy rod which operated a pump at the foot of the shaft. Steam was admitted above the piston for a short portion of the stroke, thereby raising the pump-rod, and was allowed to expand for the remainder. Then an equilibrium valve, connecting the space above and below the piston, as in fig. 6, was opened, and the pump-rod descended, doing work in the pump and raising the engine piston. The large mass which had to be started and stopped at each stroke served by its inertia to counterbalance the unequal pressure of the steam, for the ascending rods stored up energy of motion in the early part of the stroke, when the steam pressure was greatest, and gave out energy in the later part, when expansion had greatly lowered the pressure. The frequency of the stroke was controlled by a device called a cataract, consisting of a small plunger pump, in which the plunger, raised at each stroke by the engine, was allowed to descend more or less slowly by the escape of fluid below it through an adjustable orifice, and in its descent liberated catches which held the steam and exhaust valves from opening. A similar device controlled the equilibrium valve, and could be set to give a pause at the end of the piston's down-stroke, so that the pump-cylinder might have time to become completely filled. The Cornish engine is interesting as the earliest form which achieved an efficiency comparable with that of good modern engines. For many years monthly reports were published of the "duty" of these engines, the "duty" being the number of foot-pounds of work done per bushel or (in some cases) per cwt. of coal. The average duty of engines in the Cornwall district rose from about 18 millions of foot-pounds per cwt. of coal in 1813 to 68 millions in 1844; after which less effort seems to have been made to maintain a high efficiency (*Proc. Inst. C.E.*, 1863, vol. 23). In individual cases much higher results were reported, as in the Fowey Consols engine, which in 1835 was stated to have a duty of 125 millions. This (to use a more modern mode of reckoning) is equivalent to the consumption of only a little more than $1\frac{3}{4}$ lb of coal per horse-power per hour—a result surpassed by very few engines in even the best recent practice. It is difficult to credit figures which, even in exceptional instances, place the Cornish engine of that period on a level with the most efficient modern engines—in which compound expansion and higher pressure combine to make a much more perfect thermodynamic machine; and apart from this there is room to question the accuracy of the Cornish reports. They played, however, a useful part in the process of steam engine development by directing attention to the question of efficiency, and by demonstrating the advantage to be gained by high pressure and expansive working, at a time when the theory of the steam engine had not yet taken shape.

Cornish Engine.

19. The final revival of the compound engine did not occur until about the middle of the 19th century, and then several agencies combined to effect it. In 1845 M'Naught introduced a plan of improving beam engines of the original Watt type, by adding a high-pressure cylinder whose piston acted on the beam between the centre and the flywheel end. Steam of higher pressure than had formerly been used, after doing work in the new cylinder, passed into the old or low-pressure cylinder, where it was further expanded. Many engines whose power was proving insufficient for the extended machinery they had to drive were "M'Naughted" in this way, and after conversion were found not only to yield more power but to show a marked economy of fuel. The compound form was selected by William Pole for the pumping engines of Lambeth and other waterworks about 1850; in 1854 John Elder began to use it in marine engines; in 1857 E. A. Cowper added a steam-jacketed intermediate reservoir for steam between the high and low pressure cylinders, which made it unnecessary for the low-pressure piston to be just beginning when the other piston was just ending its stroke. As facilities increased for the use of high-pressure steam, compound expansion came into more general use, its advantage becoming more conspicuous with every increase in boiler pressure —until now there are few large land engines and scarcely any marine engines that do not employ it. In marine practice, where economy of fuel is a much more important factor in determining the design than it is on land, the principle of compound expansion has been greatly extended by the introduction of triple and even quadruple expansion engines, in which the steam is made to expand successively in three or in four cylinders. In locomotive engines, where other considerations are of more moment than the saving of coal, compound expansion has found some application, but its use there is comparatively rare.

Compound Engine.

20. The adaptation of the steam engine to railways, begun by Trevithick, became a success in the hands of George Stephenson, whose engine, the "Rocket," when tried along with others, in 1829, not only distanced its competitors but settled once and for all the question whether horse traction or steam traction was to be used on railways. The principal features of the "Rocket" were an improved steam-blast for urging the combustion of coal and a boiler (suggested by Booth) in which a large heating surface was given by the use of many small tubes through which the hot gases passed. Further, the cylinders, instead of being vertical as in earlier locomotives, were set in at a slope, which was afterwards altered to a position more nearly horizontal. To these features there was added later the "link motion," a contrivance which enabled the engine to be easily reversed and the amount of expansion to be readily varied. In the hands of George Stephenson and his son Robert the locomotive took a form which has been in all essentials maintained by the far heavier locomotives of to-day.

Application to Locomotives.

21. The first practical steamboat was the tug "Charlotte Dundas," built by William Symington, and tried in the Forth and Clyde Canal in 1802. A Watt double-acting condensing engine, placed horizontally, acted directly by a connecting-rod on the crank of a shaft at the stern, which carried a revolving paddle-wheel. The trial was successful, but steam towing was abandoned for fear of injuring the banks of the canal. Ten years later Henry Bell built the "Comet," with side paddle-wheels, which ran as a passenger steamer on the Clyde; but an earlier inventor to follow up Symington's success was the American, Robert Fulton, who, after unsuccessful experiments on the Seine, fitted a steamer on the Hudson in 1807 with engines made to his designs by Boulton and Watt, and brought steam navigation for the first time to commercial success.

Application to Steam-boats.

22. With improvements in the details of design and construction it gradually became practicable to use higher steam pressures and higher piston speeds, and consequently to obtain not only greater efficiency, but also a greater amount of power from engines of given bulk. In 1872 Sir F. J. Bramwell, describing the typical marine practice of that time, gave a list of engines, all compound, in which the boiler pressure ranged from 45 to 60 ℔, the mean piston speed was 350 ft. per minute, and the consumption of coal 2 to $2\frac{1}{2}$ ℔ per hour per indicated horse-power. In 1881 F. C. Marshall gave a similar list, in which the boiler pressure was 77 ℔, the speed 460 ft. per minute, and the consumption a trifle under 2 ℔. These were compound engines with expansion in two stages. The triple expansion engine, introduced by Dr A. C. Kirk in 1874, did not come into general use until after 1881. It became the normal type of marine engine, with pressures ranging, as a rule, from 150 to 200 ℔, piston speeds generally of 500 or 600 ft. per minute, but sometimes as high as 900 or 1000, and coal consumption of about $1\frac{1}{2}$ ℔ per hour per indicated horse-power. In some instances quadruple expansion has been preferred, with somewhat higher pressures, but it can scarcely be said to be established that the advantage of adding a fourth stage clearly compensates for the extra complication. Some particulars of the dimensions reached in modern practice will be given later. Several of the vessels engaged in the Transatlantic passenger service, and also a few armoured cruisers, have engines in which the twin sets together have an indicated horse-power exceeding 30,000. But even these figures are eclipsed in ships which are driven by turbine engines. The cruisers of the "Invincible" class have turbine engines of 41,000 horse-power, and the turbines of the great Cunarders "Lusitania" and "Mauretania" (1907) develop about 70,000 h.p. in propelling these ships at a speed of 25 knots. It may be questioned whether such gigantic concentrations of power for the propulsion of a ship would have been practicable had it not been for the new possibilities which the introduction of the steam turbine has opened up.

Rise in Steam Pressure and in Piston Speed.

Triple and Quadruple Expansion.

23. The invention of the steam turbine has in fact revolutionized marine engine practice, so far as fast vessels are concerned, and has supplied a formidable rival to the reciprocating engine for use on land. The steam turbine has been brought to a degree of efficiency which places it, in respect of economy in steam and coal consumption, on a somewhat higher level than the best engines of the older type in cases where a large amount of power is to be generated. Its greater simplicity, compactness and freedom from vibration are merits which have already gone far to secure for it a preference, notwithstanding the short time that has passed since it became known as a practicable engine. The largest demands for power occur in fast passenger vessels, in war-ships and in stations from which electric energy is distributed for traction or other uses; in all these cases the steam turbine is now taking the leading place. It is to the inventive genius of the Hon. C. A. Parsons that we owe not only the main idea of the modern steam turbine, but also the working out of many novel mechanical details which have been essential to success, as well as the adaptation of the turbine to marine propulsion.

Introduction of the Steam Turbine.

24. In the steam turbine, as in the water turbine (for which see HYDRAULICS), the force directly operative to do useful work is derived from the kinetic energy of the operative fluid, either by the impulse of a jet or jets sliding over movable blades, or by the reaction of orifices or guides from which the jets issue. The pressure, instead of being exerted on a piston, is employed in the first instance to set the fluid itself in motion. There is a conversion of pressure-energy into velocity-energy as a preliminary step towards obtaining the effective work of the machine. But in a steam turbine this implies velocities which are immensely greater than those with which water turbines have to deal, in consequence of the much smaller density of steam as the moving fluid. Attempts to design a steam turbine were made by numerous inventors, but fell short of practical success mainly because of the difficulty of arranging for a sufficiently high velocity in the working parts to utilize a reasonably large fraction of the kinetic energy of the steam, the principle involved being that for good efficiency the velocity of the blades should approximate to half the velocity of the jets which strike them. There is a further difficulty in getting the energy of the steam into a suitable kinetic form, namely, to get the stream of issuing particles to take a single direction, without undue dispersion, when steam is allowed to expand through an orifice from a chamber at high pressure into a space where the pressure is greatly less.

In 1889 Dr Gustaf de Laval introduced a form of steam turbine in which both of these difficulties were to a great extent overcome, partly by the special form of the nozzle used to produce the steam jet and partly by features of design which allowed an exceptionally high speed to be reached in the wheel carrying the vanes against which the steam impinged. This simple type of turbine, which will be described in a later section of this article, has met with considerable success, especially in comparatively small sizes, as an engine for driving electric generators. Its efficiency is fairly good, but it is not well adapted for work on a large scale, and it has not been applied to the propulsion of ships.

Parsons attacked the problem at an earlier date, in an entirely different way in the invention of his "compound" turbine. By dividing the whole expansion of the steam into a great number of successive and separate steps he limited the velocity acquired at each step to such an extent as to make it comparatively easy to extract the greater part of the kinetic energy, as work done upon the moving blades, without making the velocity of these blades inconveniently high. Moreover, in Parsons's compound turbine the range of pressure through which the steam expands in each separate step is too small to give rise to any difficulty in the formation of the jets. The guide blades, which form the jets, are distributed round the whole circumference of the revolving wheel, and all the revolving blades are consequently in action at once. The steam streams from end to end through an annular space between a revolving drum and the casing which surrounds it. Parallel rings of fixed guide blades project inwards from the casing at suitable distances, and between these are rings of moving blades which project outwards from the drum and revolve with it. At each step in the expansion the steam streams through a ring of fixed guide blades, and the streams so formed impinge on the next ring of moving blades, and so on. The construction, which is of great simplicity, will be described later; it lends itself well to the generation of power on a large scale, especially in cases where a fairly high speed of rotation is wanted. The more powerful the turbine the less important do various inevitable sources of loss become; and hence, though the small turbines which were first built were less economical than reciprocating engines, the advantage is the other way where large powers are concerned.

25. Parsons introduced his compound steam turbine in 1884. For some years it was made in small sizes only, and the steam was discharged to the atmosphere without condensation. So long, however, as this was done the steam turbine was sacrificing one of its most important advantages, namely, its exceptional capacity for utilizing the energy of low-pressure steam down to the lowest vacuum obtainable in a condenser. In 1891 it was first fitted with a condenser, and it then began to be used in electric supply stations. Its efficiency at that date was found, in tests made by the present writer, to be comparable with that of good reciprocating compound engines, but the figures then obtained were much improved on later in turbines of larger size and modified design. The first application to marine propulsion was in the "Turbinia," in 1897. The success of this little experimental vessel of 100 tons, which with its horse-power of 2100 made a record in speed for a ship of any size, was soon followed by the application of the turbine to various war-ships and other steamers. In war-ships the use of steam turbines has a special advantage in enabling the machinery to be kept at a low level, beneath the protective deck, in addition to the general advantages of reduced bulk, reduced vibration, reduced liability to break-down, and reduced consumption of coal and of oil which are common to vessels of all classes. The successful trials of the cruiser "Amethyst" in 1904 demonstrated these advantages so conclusively that all new war-ships for the British navy, from battleships to torpedo-boats are being fitted with steam turbines. It is also used in many cross-channel packets, as well as in the largest ocean-going passenger vessels. The turbine-driven steamers "Lusitania" and "Mauretania" (1907) are the most powerful and the fastest ocean-going vessels afloat. The rapid development of the marine steam turbine makes it probable that it will displace the reciprocating engine in all large and fast ships. For slow-going cargo-boats it is at a disadvantage, unless gearing is resorted to, on account of the difficulty of securing a sufficiently high peripheral velocity in the turbine drums without making the turbines unduly bulky, and the leakage losses (due to steam passing through the clearance spaces over the tips of the blades) unduly large. Experiments by Parsons (*Trans. Inst. Nav. Arch.*, 1910) on a ship in which a slow-running propeller is driven through reducing-gear from a high-speed turbine, have given highly promising results.

Enough has been said to show that the invention of the steam turbine is the most important step in steam engineering since the time of Watt. It is the first solution of the problem of using steam efficiently in an engine without reciprocating parts. The object in most steam engines is to deliver power to revolving machinery, and much ingenuity has been expended in attempts to devise engines which will produce rotation directly, instead of by conversion of reciprocating motion. No rotary engine, however, was permanently successful until the steam turbine took a practical form.

Theory of Steam Engine.

26. In the early development of the steam engine inventors had little in the way of theory to guide them. Watt had the advantage, which he acknowledges, of a knowledge of Joseph Black's doctrine of latent heat; but there was no philosophy of the relation of work to heat until long after the inventions of Watt were complete. The theory of the steam engine as a heat engine dates from 1824, when N. L. Sadi Carnot published his *Réflexions sur la puissance motrice du feu*, and showed that heat does work only by being let down from a higher to a lower temperature. But Carnot had no idea that any of the heat disappears in the process, and it was not until the doctrine of the conservation of energy was established in 1843 by the experiments of J. P. Joule that the theory of heat engines began a vigorous growth. From 1849 onwards the science of thermodynamics was developed with extraordinary rapidity by R. J. M. Clausius, W. J. Macquorn Rankine and William Thomson (Lord Kelvin) and was applied, especially by Rankine, to practical problems in the use of steam. The publication in 1859 of Rankine's *Manual of the Steam Engine* formed an epoch in the history of the subject by giving inventors a new basis, outside of mere empiricism, from which they could push on the development of the steam engine. Unfortunately, however, it was assumed that the cylinder and piston might be treated as behaving to the steam like non-conducting bodies—that the transfer of heat between the steam and the metal was negligibly small. Rankine's calculations of steam consumption, work and thermodynamic efficiency involve this assumption, except in the case of steam-jacketed cylinders, where he estimates that the steam in its passage through the cylinder takes just enough heat from the jacket to prevent a small amount of condensation which would otherwise occur as the process of expansion goes on. If the transfer of heat from steam to metal could be overlooked, the steam which enters the cylinder would remain during admission as dry as it was before it entered, and the volume of steam consumed per stroke would correspond with the volume of the cylinder up to the point of cut-off. It is here that the actual behaviour of steam in the cylinder diverges most widely from the behaviour which the theory assumes. When steam enters the cylinder it finds the metal chilled by the previous exhaust, and a portion of it is at once condensed. This has the effect of increasing, often very largely, the volume of boiler steam required per stroke. As expansion goes on the water that was condensed during admission begins to be re-evaporated from the sides of the cylinder, and this action is often prolonged into the exhaust. It is now recognized that any theory which fails to take account of these exchanges of heat between the steam and its metal envelope fails also to yield even comparatively correct results in calculating the relative efficiency of various steam pressures or various ranges of expansion. But the exchanges of heat are so complex that there seems little prospect of submitting them to any comprehensive theoretical treatment, and information is rather to be sought from the scientific analysis of experiments with actual machines.

27. *Formation of Steam under Constant Pressure.*—In attempting a brief sketch of steam engine theory it is necessary to begin by giving some account of the properties of steam, so far as they are relevant. The properties of steam are most conveniently stated by referring in the first instance to what happens when steam is formed *under constant pressure.* This is substantially the process which occurs in the boiler of a steam engine when the engine is at work. To fix the ideas we may suppose that the vessel in which steam is to be formed is a long upright cylinder fitted with a piston which may be loaded so that it exerts a constant pressure on the fluid below. Let there be, to begin with, at the foot of the cylinder a quantity of water (which for convenience of numerical statement we shall take as 1 lb), at any temperature t_0; and let the piston press on the surface of the water with a force of p lb per square foot. Let heat now be applied to the bottom of the cylinder. As it enters the water it will produce the following effects in three stages:—

1. The temperature of the water rises until a certain temperature t is reached, at which steam begins to be formed. The value of t depends on the particular pressure p which the piston exerts. Until the temperature t is reached there is nothing but water below the piston.

2. Steam is formed, more heat being taken in. The piston (which is supposed to exert a constant pressure) rises. No further increase of temperature occurs during this stage, which continues until all the water is converted into steam. During this stage the steam

which is formed is said to be *saturated*. The volume which the piston encloses at the end of this stage—the volume, namely, of 1 lb of saturated steam at pressure p (and temperature t)—will be denoted by v in cubic feet.

3. If after all the water is converted into steam more heat be allowed to enter, the volume will increase and the temperature will rise. The steam is then said to be *superheated*.

The difference between saturated and superheated steam may be expressed by saying that if water (at the temperature of the steam) be mixed with steam some of the water will be evaporated if the steam is superheated, but none if the steam is saturated. Any vapour in contact with its liquid and in thermal equilibrium is necessarily saturated. When saturated its properties differ considerably, as a rule, from those ot a perfect gas, especially at high pressures, but when superheated they approach those of a perfect gas more and more closely the further the process of superheating is carried, that is to say, the more the temperature is raised above t, the temperature of saturation corresponding to the given pressure p.

28. *Relation of Pressure and Temperature in Saturated Steam.*—The temperature t at which steam is formed depends on the value of p. Their relation was determined with great care by Regnault (*Mem. Inst. France*, vol. xxi.). The pressure of saturated steam rises with the temperature at a rate which increases rapidly in the upper regions of the scale. This will be apparent from the first and second columns of the following table. The first column gives the temperature on the Centigrade scale; the second gives the corresponding pressure in pounds per square inch.

29. *Relation of Volume and Temperature.*—The same table shows the volume v in cubic feet occupied by 1 lb of saturated steam at each temperature. This is based on the investigations of H. L. Callendar who has shown (see THERMODYNAMICS and VAPORIZATION) that an equation of the form

$$v=\frac{R\tau}{p}+b-c$$

is applicable to water vapour, whether saturated or superheated, within the limits of experimental error throughout the range of pressure that is important in engineering practice. In this equation τ is the absolute temperature, R and b are constants and c is a term varying inversely as a certain power of the temperature. By aid of this equation, in conjunction with the results of various experiments on the latent heat and other properties of steam, Callendar has shown that it is possible to frame expressions from which numerical values of all the important properties of steam may be derived throughout a range of saturation temperatures extending from 0° C. to 200° C. or so. The values so obtained are thermodynamically consistent with one another, and are in good agreement with the most authoritative experimental results. They are accordingly to be accepted in lieu of those given in earlier steam tables which depended on measurements by Regnault, and are now known to be in some particulars erroneous. R. Mollier has applied Callendar's method with great completeness to the calculation of steam tables, and the figures given here are adapted from his results.[1] In addition to the relation of temperature, pressure and volume, the table shows other properties of steam which will be explained as we proceed.

30. *Supply of Heat in Formation of Steam under Constant Pressure.*—We have next to consider the supply of heat in the imaginary experiment of § 27. During the first stage, until the temperature rises from its initial value t_0 to t, the temperature at which steam begins to form under the given pressure, heat is required only to warm the water. Since the specific heat of water is nearly constant, the amount of heat taken in during the first stage is approximately $t-t_0$ thermal units, or J $(t-t_0)$ foot-pounds, J being Joule's equivalent, and this expression for it will generally serve with sufficient accuracy in practical calculations. More exactly, however, the heat taken in is somewhat greater than this at high temperatures, for Regnault's experiments show that the specific heat of water increases slightly as the temperature rises. In stating the amount of heat required for this first stage, t_0 must be taken as a known temperature; for convenience in numerical statement the temperature 0° C. is usually chosen as an arbitrary starting-point from which the reception of heat is to be reckoned. We shall employ the symbol h to designate the heat required to raise 1 lb of water from 0° C. to the temperature t at which steam begins to form. During the first stage, sensibly all the heat supplied goes to increase the stock of internal energy which the fluid possesses, the amount of external work which is done by the expansion of the fluid being negligible.

The heat taken in during the second stage is what is called the *latent heat* of steam, and is denoted by L. Of it a part is spent in doing external work, namely, p multiplied by the excess of the volume of the steam v over the volume of the water w, and the remainder is the difference of internal energy between 1 lb of steam at t and 1 lb of water at t.

31. *Total Heat of Steam.*—Adding together the heat taken in during the first and second stages, we have a quantity designated by H which may be called the heat of formation of 1 lb of saturated steam:—

$$H=h+L.$$

The heat of formation of 1 lb of steam, when formed under constant pressure from water at any temperature t_0, is $H-h_0$, where h_0 corresponds to t_0.

It has been pointed out by Mollier that for the purpose of calculations in technical thermodynamics it is convenient to add to the heat of formation the quantity pw/J, which represents the thermal equivalent of the work spent in introducing the water under the piston, against the constant pressure p, before the operation of heating imagined in § 27 begins, w being the volume of the water. We thus obtain a quantity which in its numerical values differs only very slightly from H, namely

$$I=H+pw/J.$$

We shall call this the *total heat* of saturated steam. Values of I are stated in the table. Since the volume of 1 lb of water is only

0·016 cub. ft. the term pw/J is numerically insignificant except at the highest pressures. Similarly, in reckoning the total heat of water I_w we add pw/J to h, and this quantity is also given in the table. The latent heat L is to be found from the table by subtracting I_w, the total heat of water, from the total heat of steam. We shall use the centigrade scale of temperature throughout this article, and accordingly the total heats are expressed in terms of a unit involving the centigrade degree, namely, the quantity of heat required to raise the temperature of unit mass of water through 1° C. at 15° C. With this unit of heat the mechanical equivalent J is 1400 foot-pounds when the unit of mass is the lb, and is 427 kilogram-metres when the unit of mass is the kilogramme.

32. *Internal Energy.*—Of the heat of steam the part pv/J is spent in doing external work. The remainder has gone to increase the stock of internal energy which the substance possesses.

In dealing with the heat required to produce steam we adopted the state of water at 0° C. as an arbitrary starting-point from which to reckon the reception of heat. In the same way it is convenient

[1] R. Mollier, *Neue Tabellen und Diagramme fur Wasserdampf* (Berlin, 1906). See also Ewing's *Steam Engine* (3rd ed., 1910).

to use this arbitrary starting-point in reckoning what may be called the *internal energy* of the substance, which is the excess of the heat taken in over the external work done by the substance during its reception of heat. Thus the internal energy E of 1 lb of saturated steam at pressure p is equal to the total heat I, less that part of the total heat which is spent in doing external work, or

$$E = I - pv/J.$$

The notion of internal energy is useful in calculating the heat taken in or rejected by steam during any stage of its expansion or compression in an engine. When a working substance passes from one condition to another its gain or loss of heat is determined by the equation

Heat taken in = increase of internal energy + external work.

Any of the terms of this equation may be negative; the last term is negative when work is done, not by but upon the substance.

33. *Wet Steam.*—In calculations which relate to the action of steam in engines we have often to deal, not with *dry* saturated steam, but with *wet* steam, or steam which either carries in suspension, or is otherwise mixed with, a greater or less proportion of water. In any such mixture, assuming it to be in equilibrium, the steam and water have the same temperature, and the steam is saturated. The dryness of wet steam is measured by the proportion q of dry steam in each pound of the mixed substance. When that is known it is easy to determine the other physical constants: thus—

Latent heat of 1 lb of wet steam $= qL$;
Total heat of 1 lb of wet steam $= I_w + qL$;
Volume of 1 lb of wet steam $= qv + (1-q)_w$
$= qv$ very nearly,

unless the steam is so wet as to consist mainly of water.

34. *Superheated Steam.*—Steam is superheated when its temperature is raised, in any manner, above the temperature corresponding to saturation at the actual pressure. When considerably superheated, steam approximates in behaviour to a perfect gas.

The specific heat during superheating is nearly constant at low pressures, its value being approximately 0·48; at high pressures it is higher, especially when the amount of superheating is slight. Callendar's equations enable it to be calculated for any assigned conditions of temperature and pressure. They also allow a direct determination to be made of the total heat of superheated steam of given temperature and pressure, and from this. by comparison with the total heat of saturated steam at the same pressure, the mean specific heat over any stated range of superheating may be found. Calling I_s the total heat of steam in the saturated condition, when the temperature is t, κ the mean specific heat in superheating at constant pressure to a higher temperature t' and I' the total heat in the superheated state, we have

$$I' = I_s + \kappa(t' - t).$$

The following are values of κ:—

Temperature of Superheat t' in °C.	Temperature of Saturation t in °C.				
	80°	120°	160°	180°	200°
100°	0·49				
150°	0·49	0·51			
200°	0·49	0·51	0·54	0·57	
250°	0·48	0·50	0·53	0·56	0·59
300°	0·48	0·50	0·52	0·54	0·57
350°	0·48	0·49	0·51	0·53	0·56
400°	0·48	0·49	0·51	0·52	0·55
450°	0·48	0·49	0·51	0·52	0·54

35. *Isothermal Expansion of Steam.*—The expansion of volume which occurs during the conversion of water into steam under constant pressure is isothermal. From what has been already said it is obvious that steam, or any other saturated vapour, can be expanded or compressed isothermally only when wet, and that evaporation (in the one case) or condensation (in the other) must accompany the process. Isothermal lines for a working substance which consists of a liquid and its vapour are straight lines of uniform pressure.

36. *Adiabatic Expansion of Steam.*—If steam initially dry be allowed to expand adiabatically (namely, without taking in or giving out any heat) it becomes wet. A part of the steam is condensed by the process of adiabatic expansion, at first in the form of minute particles suspended throughout the mass. The temperature and pressure fall; and, as that part of the substance which remains uncondensed is saturated, the relation of pressure to temperature throughout the expansion is that which holds for saturated steam. Before expansion let the initial dryness of the steam be q_1 and its absolute temperature τ. Then, if it expand adiabatically until its temperature falls to τ, its dryness after expansion may be shown to be

$$q = \frac{\tau}{L}\left(\frac{q_1 L_1}{\tau_1} + \log_\epsilon \frac{\tau_1}{\tau}\right).$$

L_1 and L are the latent heats (in thermal units) of 1 lb of steam before and after expansion respectively. When the steam is dry to begin with, $q_1 = 1$.

This formula is easily applied to the construction of the adiabatic curve when the initial pressure and the pressure after expansion are given, the corresponding values τ and L being found from the table.

37. *Ideal Action of Heat Engine.*—According to the principles of thermodynamics (*q.v.*), the action of a heat engine depends on its receiving heat at a temperature higher than that at which it is capable of rejecting heat to surrounding objects. The working substance in the engine must necessarily pass from an upper temperature, at which it takes in heat, to a lower temperature, at which it rejects heat, the difference between the heat taken in and the heat rejected being the thermal equivalent of the work done. It may readily be shown that when the conditions are such as to make this difference as great as possible—in other words, to make the efficiency reach its ideal limit—the ratio of the heat taken in to the heat rejected depends only on the temperature at which reception and rejection of heat occur. Calling τ_1 and τ_2 the absolute temperatures at which heat is taken in and rejected respectively, and Q_1 and Q_2 the quantities of heat taken in and rejected, the limit of efficiency is reached when $Q_1/Q_2 = \tau_1/\tau_2$. The efficiency then has the value

$$(Q_1 - Q_2)/Q_1 = (\tau_1 - \tau_2)/\tau_1$$

and W, the work done, is $Q_1(\tau_1 - \tau_2)/\tau_1$.

In the ideal engine imagined by Carnot the action is of this simple character. The working substance is brought by adiabatic compression from the lower to the upper extreme of temperature. It then takes in heat, without changing in temperature. Next, it expands adiabatically until its temperature falls to the lower extreme and finally at that temperature it rejects enough heat to restore it to its initial state, thereby completing a cycle of operations.

38. *Carnot's Cycle with Steam for Working Substance.*—We are now in a position to study the action of a heat engine employing steam as the working substance. To simplify the first consideration as far as possible, let it be supposed that we have a long cylinder composed of non-conducting material except at the base, and fitted with a non-conducting piston; also a source of heat A at some temperature τ_1; a receiver of heat, or, as we may now call it, a condenser C, at a lower temperature τ_2; and a non-conducting cover B. Then we can perform as follows the ideal reversible cycle of operations first described by Carnot, which gives the highest possible efficiency attainable in any heat engine. To fix the ideas, suppose that there is 1 lb of water in the cylinder to begin with, at the temperature τ_1:—

1. Apply A, and allow the piston to rise. The water will take in heat and be converted into steam, expanding isothermally at constant pressure p_1. This part of the operation is shown by the line ab in fig. 9.

2. Remove A and apply B. Allow the expansion to continue adiabatically (bc), with falling pressure, until the temperature falls to τ_2. The pressure will then be p_2, namely, the pressure given in the table corresponding to τ_2.

3. Remove B, apply C, and compress. Steam is condensed by rejecting heat to C. The action is isothermal, and the pressure remains p_2. Let this be continued until a certain point d is reached, after which adiabatic compression will complete the cycle.

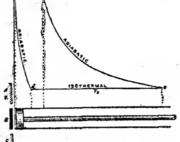

FIG. 9.—Carnot's Cycle with water and steam for working substance.

4. Remove C and apply B. Continue the compression, which is now adiabatic. If the point d has been rightly chosen, this will complete the cycle by restoring the working fluid to the state of water at temperature τ_1.

The "indicator diagram" or diagram exhibiting the relation of pressure to volume for such a cycle is given in fig. 9. Since the process is reversible, and since heat is taken in only at τ_1 and rejected only at τ_2, the ideal conditions for perfect efficiency are satisfied, and accordingly the efficiency is $(\tau_1 - \tau_2/\tau_1$. The heat taken in per lb of the fluid is L_1, and the work done is $L_1(\tau_1 - \tau_2)/\tau_1$, a result which may be used to check the calculation of the diagram.

39. *Efficiency of a Perfect Steam Engine: Limits of Temperature.*—If the action here described could be realized in practice, we should have a thermodynamically perfect steam engine using saturated steam. The fraction of the heat supplied to it which such an engine would convert into work would depend simply on the temperature, and therefore on the pressure, at which the steam was produced and condensed. The temperature of condensation is limited by the consideration that there must be an abundant supply of some substance to absorb the rejected heat; water is actually used for this purpose, so that τ_2 has for its lower limit the temperature of the available water-supply.

To the higher temperature τ_1 a practical limit is set by the mechanical difficulties, with regard to strength and to lubrication, which attend the use of high-pressure steam. In engines of ordinary construction the pressure is rarely so much as 250 lb per sq. in.

It must not be supposed that the efficiency $(\tau_1-\tau_2)/\tau_1$ is actually attained, or is even attainable. Many causes conspire to prevent steam engines from being thermodynamically perfect, and some of the causes of imperfection cannot be removed.

40. *Engine with Separate Organs.*—In the ideal engine represented in fig. 10 the functions of boiler, cylinder and condenser are combined in a single vessel; but, provided the working substance passes through the same cycle of operations, it is indifferent whether these are performed in several vessels or in one. To approach a little more closely the conditions that hold in practice, we may think of the engine as consisting of a boiler A (fig. 10) kept at τ_1, a non-conducting cylinder and piston B, a surface condenser C kept at τ_2, and a feed-pump D which restores the condensed water to the boiler. When the several organs of the engine are separated in this way we can still carry out the first three stages of the cyclic process described in § 38. The first stage of that cycle corresponds to the *admission* of steam from the boiler into the cylinder. Then the point known as the point of *cut-off* is reached, at which admission ceases, and the steam already in the cylinder is allowed to expand, exerting a diminishing pressure on the piston. This is the second stage, or the stage of *expansion*. The process of expansion may be carried on until the pressure falls to that of the condenser, in which case the expansion is said to be complete. At the end of the expansion *release* takes place, that is to say, communication is opened with the condenser. Then the return stroke begins, and a period termed the *exhaust* occurs, that is to say, steam passes out of the cylinder, into the condenser, where it is condensed at the pressure in the condenser, which is felt as a *back pressure* opposing the return of the piston. So far, all has been essentially reversible and identical with the corresponding parts of Carnot's cycle.

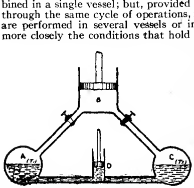

FIG. 10.—Organs of a Steam Engine.

But we cannot complete the cycle as Carnot's cycle was completed. The existence of a separate condenser makes the fourth stage, that of adiabatic compression, impracticable, and the best we can do is to continue the exhaust until condensation is complete, and then return the condensed water to the boiler.

41. *Rankine Cycle.*—It follows that the ideal cycle of Carnot is not an appropriate standard with which to compare the action of a real steam engine. Instead of it we have, in the engine with separated organs, a cycle which is commonly called the Rankine cycle, which differs from the Carnot cycle only in this, that the stage of adiabatic compression, is wanting and its place is taken by a direct return of the condensed water to the boiler, a process which makes the water receive heat at various temperatures, ranging from the temperature of the condenser up to that of the boiler. The chief part of the heat which the working substance receives is still taken in at the upper limit of temperature, during the process of changing from water to steam. But a small part is taken in at lower temperatures, namely, in the heating of the feed water in its transfer to the boiler. Any heat so taken in has less availability for conversion into work than if it were taken in at the top of the range, and consequently the ideal efficiency of the cycle falls somewhat short of this ideal reached in the cycle of Carnot.

But the principle still applies that with respect to each portion of the heat that is taken in, the fraction convertible into work under ideally favourable conditions is measured by $(\tau-\tau_2)/\tau$, where τ is the absolute temperature at which that portion of heat is received, and τ_2 is the temperature at which heat is rejected. Accordingly, we may investigate as follows the ideal performance of an engine following the Rankine cycle. Let δQ represent that portion of the whole heat which is taken in at any temperature τ. Then the greatest amount of work obtainable from that portion of heat is $\delta Q(\tau-\tau_2)/\tau$, and the whole amount of work ideally obtainable in the complete process is found by calculating $\Sigma\delta Q(\tau-\tau_2)/\tau$ where the summation includes all the heat that is taken in. In a steam engine using saturated steam the principal item in this sum is the latent heat L_1, which is taken in at constant temperature τ_1, during the change of state from water to steam. But there is, in addition, the heat taken in by the feed-water before it reaches the temperature at which steam is formed, and this may be represented as the sum of a series of elements $\sigma\delta\tau$ taken in at varying temperatures τ, where σ is the specific heat of water. Thus if W represents the thermal equivalent of the work theoretically obtainable per lb of steam, under ideally favourable conditions,

$$W=\Sigma\frac{\sigma\delta\tau(\tau-\tau_2)}{\tau}+\frac{L_1(\tau_1-\tau_2)}{\tau_1}.$$

The experiments of Regnault show that σ, within the limits of temperature that obtain in boilers, is a nearly constant quantity, and no serious error will be introduced in this integration by treating it as a constant, with a value equal to the mean value, as determined by Regnault, between the limits of τ_1 and τ_2. On this basis

$$W=\sigma(\tau_1-\tau_2)-\sigma\tau_2\log_\epsilon\frac{\tau_1}{\tau_2}+\frac{L_1(\tau_1-\tau_2)}{\tau_1}.$$

It is usual to take σ as practically equal to 1, which makes

$$W=(\tau_1-\tau_2)\left(1+\frac{L_1}{\tau_1}\right)-\tau_2\log_\epsilon\frac{\tau_1}{\tau_2}.$$

This expresses the greatest amount of work which each pound of steam can yield when the temperature τ_1 at which it reaches the engine and the temperature τ_2 at which it leaves the engine are assigned. It consequently serves as a standard with which the actual performance may usefully be compared. The actual yield per lb of steam is always considerably less, chiefly because the ideal condition of adiabatic expansion from the higher to the lower extreme of temperature is never satisfied.

A more simple expression for the work theoretically obtainable per lb of steam when expanded adiabatically under the conditions of the Rankine cycle, is

$$I_1-I_2,$$

where I_1 is the total heat of the working substance in the initial state, before the adiabatic expansion, and I_2 is its total heat after that expansion. For it may readily be proved that, in an adiabatic process,

$$I_1-I_2=\frac{1}{J}\int_{p_2}^{p_1}vdp,$$

and this integral is the area of the indicator diagram when the substance is taken in at p_1, expanded to p_2 and discharged at p_2.

This expression applies whether the steam is initially superheated or not. I_2 will in general be the total heat of a wet mixture, and to calculate it we must know the condition as to wetness which results from the expansion. This is most easily found, especially when there has been initial superheat, by making use of the entropy-temperature diagram to be presently described, or by other graphic methods, for an account of which the reader should refer to the paper by Mollier already cited, or to J. A. Ewing's *The Steam Engine and other Heat Engines* (3rd ed.).

42. *Entropy.*—The study of steam-engine problems is greatly assisted by introducing the idea of entropy and making use of diagrams in which the two co-ordinates are entropy and temperature. Entropy is a condition of the working substance defined by the statement that when any quantity of heat δQ is received by, or generated in, or rejected by the substance, when its absolute temperature is τ, the substance gains or loses entropy by the amount $\delta Q/\tau$. Thus $\Sigma\delta Q/\tau$ measures the whole change of entropy in a process which involves the taking in or rejection of heat at more than one temperature. We shall denote entropy by ϕ, and consider it as reckoned per unit of mass of the substance. Since by definition of entropy $\delta\phi=\delta Q/\tau$, $\tau\delta\phi=\delta Q$, and hence if a curve be drawn with τ and ϕ for ordinates to exhibit the action of a working substance, the area under the curve, or $\int\tau d\phi$, being equal to $\Sigma\delta Q$, measures the heat which the substance has received or rejected during the operation which the curve represents.

In a reversible cycle of operations Carnot's principle shows that $\Sigma\delta Q/\tau=0$, and it is obvious in such a case that the entropy returns at the end of the cycle to its primitive value. The same result may be extended to a cycle which includes any non-reversible step, by taking account of the heat generated within the substance by such a step, as if it were heat communicated from outside, in the reckoning of entropy. Thus, for example, if at one stage in the cycle the substance passes through a throttle-valve, which lowers its pressure without letting it do work, the action is equivalent in effect to an adiabatic expansion, together with the communication to the substance, as heat, of the work which is lost in consequence of the irreversible expansion through the throttle-valve taking the place of adiabatic expansion against a piston. If this heat be included in the reckoning $\Sigma\delta Q/\tau=0$ for the complete cycle.

The entropy-temperature diagram for any complete cyclic process is a closed curve, and the area it encloses, being the excess of the heat received over the heat rejected, measures the work done. The entropy-temperature diagram shares this useful characteristic with the pressure-volume diagram, and in addition it shows directly the heat received and the heat rejected by the areas under the forward and backward limbs of the curve. To draw the entropy-temperature diagram for the ideal steam engine (namely, the engine following the Rankine cycle), we have to reckon first the entropy which water acquires in being heated, and next the entropy L_1/τ_1 which is acquired when the conversion into steam has taken place. Reckoning from any standard temperature τ_0, in the heating of the feed-water up to any temperature τ, the entropy acquired is

$$\phi_w=\int_{\tau_0}^{\tau}\frac{\sigma d\tau}{\tau},$$

and taking σ as sensibly constant,

$$\phi_w=\sigma(\log_\epsilon\tau-\log_\epsilon\tau_0).$$

During evaporation at τ_1 a quantity of heat L_1 is taken in at temperature τ_1, and hence the entropy of the steam

$$\phi_s=\phi_w+L_1/\tau_1=\sigma(\log_\epsilon\tau_1-\log_\epsilon\tau_0)+L_1/\tau_1.$$

Values of the entropy of water and steam are given in the table. The entropy-temperature diagram for a Rankine cycle is illustrated in fig. 11, where ab, a logarithmic curve, represents the process of heating the feed-water, and bc the passage from the state of water into that of steam. The diagram is drawn to scale for a case in which steam is formed at a pressure of 180 ℔ per sq. in., and condensed at a pressure of 1 ℔ per sq. in. After the formation of the steam, the next step in the ideal process is adiabatic expansion from the higher to the lower limit of temperature, which is represented by the vertical straight line cd, an adiabatic process being also isentropic. Finally, the cycle is completed by da, which represents the condensation of the steam after its temperature has been reduced by adiabatic expansion to the lower limit of temperature. The area $abcd$ represents the work done, and its value per ℔ of steam is identical with W as reckoned above. The area $mabcp$ is the whole heat taken in, and the area $madp$ is the heat rejected.

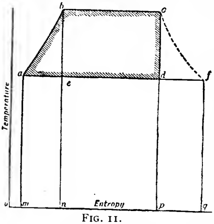

FIG. 11.

Let a curve cf be drawn to show the values of the entropy of steam for various temperatures of saturation: then if ad be produced to meet the curve in f, the ratio fd/fa represents the fraction of the steam which was condensed during adiabatic expansion. For the point f represents the state of 1 ℔ of saturated steam, and in the condensation of 1 ℔ of saturated steam the heat given out would be the area under fa, whereas the heat actually given out in the condensation from d was the area under da. Thus the state at d is that of a wet mixture in which da/fa represents the fraction present as steam, and fd/fa the fraction present as water. It obviously follows that by drawing horizontal lines at intermediate temperatures the development of wetness in the expanding steam can be readily traced. Again, if the steam is not dry when expansion begins, its state may be represented by making the expansion line begin at a point in the line bc, such that the segments into which the line is divided are proportional to the constituents of the wet mixture. In this way the ideal process may be exhibited for steam with any assumed degree of initial wetness. Further, the entropy-temperature diagram admits of ready application to the case of incomplete expansion. Suppose, for example, that after adiabatic expansion from c to c' (fig. 12) the steam is directly cooled to the lower-limit

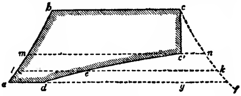

FIG. 12.

temperature by the application of cooling water instead of by continued expansion. This process is represented by the line $c'ed$, which is a curve of constant volume. Its form is determined by the consideration that at any point e the proportion of steam still uncondensed, or le/lk, is such that the mixture fills the same volume as was filled at c'.

43. *Entropy-Temperature Diagrams extended to the Case of Superheated Steam.*—In the diagrams which have been sketched, it has been assumed that the steam is supplied to the engine in a saturated state. To extend the same treatment to the case of superheated steam, we have to take account of the supplementary supply of heat which the steam receives after the point c is reached, and before expansion begins. When superheating is resorted to, as is now often the case in practice, the superheat is given at constant pressure. If κ represent as before the mean specific heat of steam at constant pressure, the addition of entropy during

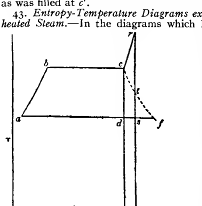

FIG. 13.

the process of superheating from τ_1 to τ' is $\kappa(\tau'-\tau_1)$. The value of κ may be treated as approximately constant, and the addition to the entropy may then be written as $\kappa(\log\tau'-\log\tau_1)$. This gives a line such as cr on the entropy diagram (fig. 13), and increases the value of W by the amount

$$\int_{\tau_1}^{\tau'} \frac{\kappa d\tau(\tau-\tau_2)}{\tau}$$

which is represented on the diagram by the area $dcrs$. During adiabatic expansion from r the steam remains superheated until it reaches the state t, when it is just saturated, and further expansion results in the condition of wetness indicated by s. The extra work $dcrs$ is done at the expense of the extra supply of heat $pcru$, and an inspection of the diagram suffices to show that the efficiency of the ideal cycle is only very slightly increased by even a large amount of superheating. In practice, however, superheating does much to promote efficiency, because it materially reduces the amount by which the actual performance of an engine falls short of the ideal performance by keeping the steam comparatively dry in its passage through the engine, and thereby reducing exchanges of heat between the steam and the metal.

44. *Entropy of Wet Steam.*—The entropy of *wet* steam is readily calculated by considering that the change of entropy in the conversion from water to steam will be qL/τ if the steam is wet, q being the dryness. Accordingly the entropy of wet steam at any temperature τ is $\sigma(\log_\epsilon\tau-\log_\epsilon\tau_0)+qL/\tau$. Further, since σ for water is practically equal to unity this expression may be written

$$\phi=\log_\epsilon\tau-\log_\epsilon\tau_0+qL/\tau.$$

We may apply this expression to trace the development of wetness in steam when it expands adiabatically. In adiabatic expansion ϕ=constant. Using the suffix 1 to distinguish the initial state, we therefore have at any stage in the expansion

$$\log_\epsilon\tau-\log_\epsilon\tau_0+qL/\tau=\log_\epsilon\tau_1-\log_\epsilon\tau_0+q_1L_1/\tau_1,$$

from which the dryness at that stage is found, namely,

$$q=\frac{\tau}{L}\left(\frac{q_1L_1}{\tau_1}+\log_\epsilon\frac{\tau_1}{\tau}\right).$$

The expression is not applicable to steam which is initially superheated. In either case the graphic method of tracing the change of condition during adiabatic expansion is available.

45. *Actual Performance.*—Trials of engines using saturated steam show that in the most favourable cases from 60 to 65 % of the ideally possible amount of work is realized as "indicated" work. One of the causes of loss is that the expansion is incomplete. In practice the steam is allowed to escape to the condenser, while its pressure is still considerably higher than the pressure at which condensation is to take place. When the pressure of steam in the cylinder has been so far reduced by expansion that it can only overcome the friction of the piston, there is no advantage in going on further; the indicated work due to any additional expansion would add nothing to the output of the engine, when allowance is made for the work spent on friction within the mechanism itself. Considerations of bulk often lead to an even earlier release of the expanding steam; and another consideration which points the same way is that when expansion is carried very far, the losses due to exchange of heat between the cylinder and the steam, referred to below, tend to increase. Again, since experience shows that the most efficient engines are those in which the process of expansion is divided into two, three or more stages by the use of compounded cylinders, a certain amount of loss is to be ascribed to the drops in pressure which are liable to occur through unresisted expansion in the transfer of steam from one vessel to another. But the chief cause of loss is to be found in the exchanges of heat which take place between the steam and the metal. In each cylinder there is a process of alternate condensation and re-evaporation—condensation during the period of admission, when the steam finds itself brought into contact with metal which has been chilled by evaporation during the preceding exhaust stroke, and then evaporation, when the pressure has fallen sufficiently, during the later stage of expansion, as well as during exhaust. The consequence is that the steam, though supplied in a dry state, may contain some 20 or 30 % of moisture when admission to the cylinder is complete, and the entropy diagram for the real process of expansion takes a form such as is indicated by the line $c'c''$ in fig. 14. The heat supplied is still measured by the area under abc. The condensation from c to c' occurs by contact with the walls of the cylinder; and though part of the heat thus abstracted is restored before release occurs at c'', the general result is to make a large reduction in the area of the diagram.

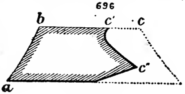

FIG. 14.

46. *Exchanges of Heat between the Steam and the Metal.*—The exchanges of heat between steam and metal in the engine cylinder have been made the subject of an elaborate experimental examination

by Professors Callendar and Nicolson (*Proc. Inst. C.E.* cxxxi. 147), who studied the cyclic variations of temperature throughout the metal by means of thermo-electric junctions set at various depths. They found that the range of temperature through which the surface of the metal fluctuates is much less than the range of temperature passed through by the steam; the processes of condensation and re-evaporation are slow, and the time is too short to bring the surface of the metal into anything like equilibrium with the steam. The amount of condensation up to the point of cut-off, as inferred from the heat which the metal takes up, may be much less than the "missing quantity" or difference between the steam supplied per stroke and the dry steam then present. According to their experiments, this discrepancy is accounted for by leakage of steam past the valve, direct from the steam chest to the exhaust, and they suggest that this source of error may have been present in many estimates of initial condensation based on determinations of the missing quantity. This may explain cases in which the initial condensation has apparently been excessive, but large amounts of initial condensation certainly do occur, and constitute the most potent factor in making the real performance of the engine fall short of the ideal standard.[1]

In the alternate condensation and re-evaporation of steam in the cylinder more heat is given to the metal by each pound of steam that is condensed than is taken from the metal by each pound of steam that is re-evaporated, the temperature of condensation being higher than that of re-evaporation. The quantity H_1-H_2, namely, the difference in the heat of formation at the two temperatures, represents this excess of heat. Unless this is in some way abstracted from the metal, the process cannot occur. Hence the action of the cylinder walls in causing alternate condensation and re-evaporation to occur may be limited by imposing conditions which prevent or reduce the abstraction of heat. By the use of a steam jacket the metal may be prevented from losing heat externally, and may even be made to take up heat. Under these conditions the action depends on the fact that more water is re-evaporated than is condensed. To some extent this is a necessary result of the work done during expansion, which (in an adiabatic process) would make the steam become wetter as expansion proceeds, and would therefore leave more water to be evaporated than is initially condensed by the action of the cylinder walls. But it is important to notice that any water which is introduced into the cylinder along with the steam will be an important factor in supplying the means by which this thermal balance is maintained. With steam that is perfectly dry before admission the action of the walls takes its limit from the condensation which expansion brings about; with steam that is wet before admission no such limit applies. Hence the importance of having steam that is initially dry. To secure this, no method is so certain as to give some initial superheat to the steam, and hence arises the practical advantage which even a small amount of superheating is found to bring about.

47. *Influence of the Slide-Valve.*—To a considerable extent the slide-valve itself promotes initial condensation, for it requires that the hot steam shall enter the cylinder through a passage which, immediately before, was chilled by being used for the escape of exhaust steam. The use of entirely distinct admission and exhaust ports and valves tends towards economy of steam, partly for this reason and partly because it allows the clearance spaces to be reduced. Accordingly, we find that many of the best recorded results of tests relate to engines in which each cylinder has four separate valves of the Corliss or of the drop type. By using horizontal cylinders with admission valves on the top and exhaust valves below, the further advantage of drainage through the exhaust valves is secured. Water which is present at release has then the chance of escaping without being re-evaporated, a circumstance which contributes largely to reduce the exchange of heat between the working substance and the metal. Thus a horizontal triple-expansion engine with drop valves, by Messrs Sulzer, using saturated steam at an absolute pressure of 160 ℔ per sq. in., and indicating not much more than 200 h.p., is reported, in a test by Professor Stodola, to have used only 11·52 ℔ of steam per indicated horse-power-hour (see *Engineer*, July 1, 1898; also summary of trials by B. Donkin, ibid., Oct. 13, 1899). The performance in this test is equivalent to nearly 69% of the ideal, an exceptionally high figure. In one or two trials of larger engines even this performance has been surpassed, 11·2 and 11·3 ℔ per horse-power-hour having been recorded. In other particularly favourable records of trials the consumption of steam with triple-expansion engines has been found to lie between 12 and 13 ℔ per horse-power-hour. Some of the best results relate to slow-running pumping engines fitted with steam jackets on the barrels and on the covers of the cylinders, and may be taken as showing how influential, in a long-period engine, the jacket may prove in reducing the evils of initial condensation. In the mean of several apparently authoritative trials by different observers on different engines the consumption of steam was 12·2 ℔ per horse-power-hour, at an absolute pressure of about 140 ℔ per sq. in., which corresponds to 66% of the ideal performance. It should be added that these figures are exceptional. A consumption of 13 or 14 ℔ of steam per horse-power-hour is much more usual even in large and well-designed triple-expansion engines; and with two-cylinder compound engines, using steam with an absolute pressure of 100 or 120 ℔ per sq. in., anything from 14 to 15 ℔ may be reckoned a good performance.

48. *Superheated Steam.*—The advantage of superheated steam, which arises mainly from its influence in reducing the exchange of heat between the steam and cylinder walls, was demonstrated by the experiments of Hirn, and as early as 1860 it was not unusual to supply superheaters with marine engines. But the practice of superheating was soon abandoned, chiefly on account of difficulties in regard to lubrication. By the introduction of heavy mineral oils this objection has been removed, and a revival in the use of superheating has taken place, with striking effect on the thermodynamic economy of engines. Experiments made in 1892 by the Alsatian Society of Steam Users on a large number of engines showed that superheating effected an average saving in coal to the extent of about 20%, when the superheater was simply placed in the boiler flue, so that it utilized what would otherwise be waste heat, and about 12% when the superheater was separately fired. In those cases the steam was superheated only about 30° to 45° C. above the temperature of saturation, but in more recent practice much greater amounts of superheat have been successfully applied. Professor Schröter has tested a factory engine of 1000 h.p., using steam superheated by some 50° C., and has shown that this amount of superheat is not sufficient to prevent some of the steam from becoming condensed on the walls during admission to the cylinder (*Zeitschrift des Vereins deutscher Ingenieure*, vol. xl., 1896). It follows that still larger amounts of superheat will be thermodynamically advantageous. That this is the case has been demonstrated by the remarkable results which have been obtained with highly superheated steam by W. Schmidt in stationary engines and locomotives. Using a somewhat special design, Schmidt has shown that it is perfectly practicable to employ steam superheated to a temperature of 400° C., and that an efficiency not attainable from steam in any other way is thereby reached. In several authentic trials of Schmidt engines the consumption of steam has been considerably less than 10 ℔ per indicated horse-power-hour—a figure which, after allowance is made for the heat taken up during the process of superheating, represents a better performance than that of the best engines using saturated or slightly superheated steam. It has been found that the consumption of coal, in the boiler and superheater together, need not exceed 1⅓ ℔ per indicated horse-power even with engines of small power. To attain this remarkable result it is of course necessary that, after the hot gases from the furnace have passed the superheater, a further extraction of heat from them should take place. This is done by an economizer or feed-water heater of peculiar form, consisting of a long coil of small pipes which maintain a circulation of hot distilled water through a closed system containing an external coil, which forms the heater of a tank through which the feed-water passes on its way to the boiler. Some of the Schmidt engines adopt the principle of single action, to escape the necessity of having a piston-rod and gland on the side which is exposed to contact with high-temperature steam; but it is found that this precaution is not essential, and that with glands of suitable design a double-acting piston may be used without inconvenience, and without risk of undue wear. In some instances Schmidt transfers to the partially expanded steam in the intermediate receiver a portion of the heat which is conveyed to the engine by the highly superheated steam; and when this is done, the steam may properly receive a still higher degree of initial superheat. Accordingly, though the initial temperature of the steam may be 400° C. or more, this is reduced to about 320° by transfer to steam in the superheater before the high-pressure steam is admitted to the cylinder. In tests by the present writer of a Schmidt plant indicating 180 h.p., in which this device was employed, the steam was superheated to 397° C. and 10·4 ℔ were used per horse-power-hour. In this trial the temperature of the chimney gases was reduced, by the use of Schmidt's feed-water heater, to 175° C., and the consumption of coal was 1·31 ℔ per indicated horse-power-hour. In another trial, of a larger engine with steam superheated to 425° C., the consumption of steam per horse-power-hour was only 9·0 ℔.

49. *The Indicator.*—The actual behaviour of steam in the cylinder of a steam engine is studied by means of the indicator, which serves not only to measure the work done but to examine the operation of the valves and generally to give much useful information regarding the action of the engine. The indicator, which was invented by Watt, and improved by Richards, is a device for automatically drawing a diagram showing the pressure at all points of the piston's stroke. In its most usual form it consists of a small steam cylinder fitted with a piston which slides easily within it and is pressed down by a spiral spring of steel wire. The cylinder of the indicator is connected by a pipe below this piston to one or other end of the cylinder of the engine, so that the piston of the indicator rises and falls in response to the fluctuations of pressure which occur in the engine cylinder. The indicator piston actuates a pencil, which rises and falls with it and traces the diagram on a sheet of paper fixed to a drum that is caused to rotate back and forth through a certain arc, in unison with the motion of the engine piston. In

[1] See also "Report of Steam Engine Research Committee," *Inst. Mech. Eng.* (1905).

M'Naught's indicator the pencil is directly attached to the indicator piston, in Richards's the pencil is moved by means of a system of links so that it copies the motion of the piston on a magnified scale. This has the advantage that an equally large diagram is drawn with much less movement of the piston, and errors which are caused by the piston's inertia arc consequently reduced. In high-speed engines especially it is important to minimize the inertia of the indicator piston and the parts connected with it. In Richards's indicator the linkage employed to multiply the piston's motion is an arrangement similar to the parallel motion introduced by Watt as a means of guiding the piston-rod in beam engines. In several recent forms of indicator lighter linkages are adopted, and other changes have been made with the object of fitting the instrument better for high-speed work. One of these modified forms of Richards's indicator (the Crosby) is shown in fig. 15. The pressure

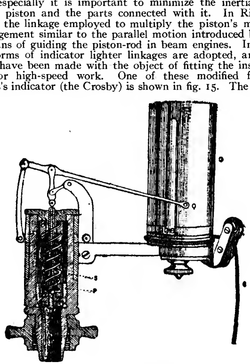

FIG. 15.—Crosby Indicator.

of steam in the engine cylinder raises the piston P, compressing the spring S and causing the pencil Q to rise in a nearly straight line through a distance proportional, on a magnified scale, to the compression of the spring and therefore to the pressure of the steam. At the same time the drum D, which carries the paper, receives motion through the cord C from the crosshead of the engine. Inside this drum there is a spiral spring which becomes wound up when the cord is pulled, and serves to turn the drum in the reverse direction during the back stroke. The cap of the indicator cylinder has holes in it which admit air freely to the top of the piston, and the piston has room to descend, extending the spring S, when the pressure of the steam is less than that of the atmosphere. The spring is easily taken out and replaced by a more or less stiff one when higher or lower pressures have to be dealt with.

50. *Errors in Indicator Diagrams.*—To register correctly, an indicator must satisfy two conditions: (1) the motion of the piston must be proportional to the change of steam pressure in the engine cylinder: and (2) the motion of the drum must be proportional to that of the engine piston.

The first of these requires that the pipe which connects the indicator with the cylinder should be short and of sufficient bore, and that it should open in the cylinder at a place where the pressure in it will not be affected by the kinetic action of the inrushing steam. Frequently pipes are led from both ends of the cylinder to a central position where the indicator is set, so that diagrams may be taken from either end without shifting the instrument; better results are obtained, especially when the cylinder is long, by using a pair of indicators, each fixed with the shortest possible connecting pipe. The general effect of an insufficiently free connexion between the indicator and the engine cylinder is to make the diagram too small. The first condition is also invalidated to some extent by the friction of the indicator piston, of the joints in the linkage, and of the pencil on the paper. The piston must slide very freely; nothing of the nature of packing is permissible, and any steam that leaks past it must have a free exit through the cover. The pencil pressure must not exceed the minimum which is necessary for clear marking. Another source of disturbance is the inertia of the moving parts, which tends to set them into oscillation whenever the indicator piston suffers a comparatively sudden displacement. These oscillations, superposed upon the legitimate motions of the piston, give a wavy outline to parts of the diagram, especially when the speed is great. When they appear on the diagram a continuous curve should be drawn midway between the crests and hollows of the undulations. To keep them within reasonable compass in high-speed work a stiff spring must be used and an indicator with light parts should be selected. Care must be taken that the spring is graduated to suit the temperature (about 100° C.) to which it is exposed when in use; its stiffness at this temperature is about 3 % less than when cold.

51. *Measurement of Horse-Power.*—To determine the indicated horse-power, the mean effective pressure is found by dividing the area of the diagram by the length of its base. This gives a mean height, which, interpreted on the scale of pressures, is the mean effective pressure in pounds per square inch. This has to be multiplied by the effective area of the piston in square inches and by the length of the piston stroke in feet to find the work done per stroke in foot-pounds on that side of the piston to which the diagram refers. Let A_1 be the area of the piston on one side and A_2 on the other; p_1 and p_2 the mean effective pressures on the two sides respectively; L the length of the stroke in feet; and n the number of complete double strokes or revolutions per minute. Then the indicated horse-power

$$\text{I.H.P.} = \frac{n\text{L}(p_1\text{A}_1 + p_2\text{A}_2)}{33000}.$$

In finding the mean pressure the area of the diagram may be conveniently measured by a planimeter. A less accurate plan, frequently followed, is to divide the diagram by lines drawn at the middle of strips of equal width and to take the mean pressure as the average height of these lines.

52. *Tests of Efficiency.*—In testing the actual efficiency of an engine the work done as determined by the indicator is compared with the supply of heat, which is calculated from the amount of steam passing through the engine. We may find the amount of steam passing through either by measuring the feed-water or, when a surface condenser is used, by collecting the condensed water from the air-pump discharge and measuring that, adding the water drained from jackets if any are used. In some trials both of these measurements have been made, and it has been found that in general the amount of feed-water exceeds the amount of steam discharged from air-pump and jackets by something like 3 or 4 %, a discrepancy due to leakages in the boiler and the engine. The results of tests are generally stated by giving the number of pounds of steam used per horse-power-hour, or by giving the work done by each pound of steam, a quantity which is directly comparable with the amount of work ideally obtainable, if the engine followed the perfect Rankine cycle already discussed. To make a complete engine trial the engine is caused to work not only at full power, but at various fractions of its greatest load. The results are very conveniently represented (in a manner due to P. W. Willans) by drawing a curve, the co-ordinates of which are the horse-power and the total consumption of steam per hour. This " Willans Line," as it is called, is in most cases straight or nearly straight. Another useful curve is drawn by plotting the steam used per horse-power-hour in relation to the horse-power.

53. *Determination of the "Missing Quantity."*—When the amount of steam passing through the engine is known, the indicator diagram enables the degree of wetness of the steam to be estimated at various stages in the expansion from cut-off to release, provided there is no direct passage from steam-chest to exhaust, such as has been referred to above in connexion with Messrs Callendar and Nicolson's researches. For this purpose we must first calculate the quantity of the working substance present in the cylinder. It is made up of two parts, namely, the amount supplied per stroke, *plus* the amount retained by being shut up in the clearance space. If we assume, as may generally be done without serious error, that at the beginning of compression the steam present in the cylinder is dry, it is an easy matter to deduce from the diagram, knowing the pressure and the volume, how much steam is shut up in the clearance. Adding that to the supply per stroke, we get the whole quantity that is present from cut-off to release. The volume which this would occupy at each pressure, if saturated, is found from the steam table. The volume actually occupied at each pressure is found from the diagram, and by comparing the two it is easy to infer how much of the substance exists as water and how much as steam. The ratio of the two volumes measures with sufficient accuracy the dryness of the steam. Any direct leakage from the steam side to the exhaust side of the valve will invalidate this calculation, which proceeds on the basis that all the steam passing through the engine passes through the cylinder.

54. *Compound Engines.*—In the original form of compound engine, invented by Hornblower and revived by Woolf, steam passed directly from the first to the second cylinder; the exhaust from the first and admission to the second went on together throughout the whole of the back stroke. This arrangement is possible only when the high and low pressure pistons begin and end their strokes together, as in engines of the " tandem " type, whose high and low pressure cylinders are in one line, with one piston-rod common to both pistons. Engines in which the high and low pressure cylinders are placed side by side, and act either on the same crank or on cranks set at 180° apart, may also discharge steam directly from one to the other cylinder; the same remark applies to beam engines, whether of the class in which both pistons act on one end of the beam, or of the class introduced by M'Naught, in which the high and low pressure cylinders stand on opposite sides of the centre. By a

convenient usage which is now pretty general the name "Woolf engine" is restricted to those compound engines which discharge steam directly from the high to the low pressure cylinders without the use of an intermediate receiver.

55. *Receiver Engine.*—An intermediate receiver becomes necessary when the phases of the pistons in a compound engine do not agree With two cranks at right angles, for example, a portion of the discharge from the high-pressure cylinder occurs at a time when the low-pressure cylinder cannot properly receive steam. The receiver is in some cases an entirely independent vessel connected to the cylinders by pipes; very often, however, a sufficient amount of receiver volume is afforded by the valve casings and the steam pipe which connects the cylinders. The receiver, when it is a distinct vessel, is frequently jacketed.

A receiver is frequently applied with advantage to beam and tandem compound engines Communication need not then be maintained between the high and low pressure cylinders during the whole of the stroke, admission to the low-pressure cylinder is stopped before the stroke is completed; the steam already admitted is allowed to expand independently; and the remainder of the discharge from the high-pressure cylinder is compressed into the intermediate receiver. Each cylinder has then a definite point of cut-off, and by varying these points the distribution of work between the two cylinders may be adjusted at will. In general it is desirable to make both cylinders of a compound engine contribute equal quantities of work. If they act on separate cranks this has the effect of giving the same value to the mean twisting moment of both cranks.

56. *Compound Diagrams.*—Wherever a receiver is used, care should be taken that there should not be a wasteful amount of unresisted expansion into it; in other words, the pressure in the receiver should be not greatly less than that in the high-pressure cylinder at the moment of release. If the receiver pressure is less there will be what is termed "drop" in the steam pressure between the high-pressure cylinder and the receiver, which will show itself in an indicator diagram by a sudden fall at the end of the high-pressure expansion. This "drop" is, from the thermodynamic point of view, irreversible, and therefore wasteful. It can be avoided by selecting a proper point of cut-off in the low-pressure cylinder. When there is no "drop" the expansion that occurs in a compound engine has precisely the same effect in doing work as the same amount of expansion in a simple engine would have, provided the law of expansion be the same in both and the waste of energy which occurs by the friction of ports and passages in the transfer of steam from one to the other cylinder be negligible. The work done in either case depends merely on the relation of pressure to volume throughout the process; and so long as that relation is unchanged it is a matter of indifference whether the expansion be performed in one vessel or in more than one. In general a compound engine has a thermodynamic advantage over a simple engine using the same pressure and the same expansion, inasmuch as it reduces the exchange of heat between the working substance and the cylinder walls and so makes the process of expansion more nearly adiabatic. The compound engine has also a mechanical advantage which will be presently described. The ultimate ratio of expansion in any compound engine is the ratio of the volume of the low-pressure cylinder to the volume of steam admitted to the high-pressure cylinder. Fig. 16 illustrates the combined action of the two cylinders in a hypothetical compound engine of the Woolf type, in which for simplicity the effect of clearance is neglected and also the loss of pressure which the steam undergoes in transfer from one to the other cylinder. ABCD is the indicator diagram of the high-pressure cylinder. The exhaust line CD shows a falling pressure in consequence of the increase of volume which the steam is then undergoing through the advance of the low-pressure piston. EFGH is the diagram of the low-pressure cylinder drawn alongside of the other for convenience in the construction which follows. It has no point of cut-off; its admission line is the continuous curve of expansion EF, which is the same as the high-pressure exhaust line CD, but drawn to a different scale of volumes. At any point K, the actual volume of the steam is KL + MN. By drawing OP equal to KL + MN, so that OP represents the whole volume, and repeating the same construction at other points of the diagram, we may set out the curve QPR, the upper part of which is identical with BC, and so complete a single diagram which exhibits the equivalent expansion in a single cylinder.

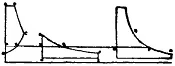

FIG. 16.—Compound Diagrams: Woolf type.

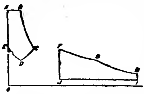

FIG. 17.—Compound Diagrams: Receiver type.

In a tandem compound engine of the receiver type the diagrams resemble those shown in fig. 17. During CD (which corresponds to FG) expansion is taking place into the large or low-pressure cylinder. D and G mark the point of cut-off in the large cylinder, after which GH shows the independent expansion of the steam now shut within the large cylinder, and DE shows the compression of steam by continued discharge from the small cylinder into the receiver. At the end of the stroke the receiver pressure is OE, and if there is to be no "drop" this must be the same as the pressure at C. Diagrams of a similar kind may be sketched without difficulty for the case of a receiver engine with any assigned phase relation between the pistons.

57. *Adjustment of Work and "Drop."*—By making the cut-off take place earlier in the large cylinder we increase the mean pressure in the receiver; the work done in the small cylinder is consequently diminished. The work done in the large cylinder is correspondingly increased, for the total work (depending as it does on the initial pressure and the total ratio of expansion) is unaffected by the change. The same adjustment serves, in case there is "drop," to lessen it. By selecting a suitable ratio of cylinder volumes to one another and to the volume of the receiver, and also by choosing a proper point for the low-pressure cut-off, it is possible to divide the work suitably between the cylinders and at the same time prevent the amount of drop from being greater than is practically convenient.

58. *Uniformity of Effort in a Compound Engine.*—An important mechanical advantage belongs to the compound engine in the fact that it avoids the extreme thrust and pull which would have to be borne by the piston-rod of a single-cylinder engine working at the same power with the same initial pressure and the same ratio of expansion. If all the expansion took place in the low-pressure cylinder, the piston at the beginning of the stroke would be exposed to a thrust much greater than the sum of the thrusts on the two pistons of a compound engine in which a fair proportion of the expansion is performed in the small cylinder. The mean thrust throughout the stroke in a tandem engine is of course not affected by compounding; only the range of variation in the thrust is reduced. The effort on the crank-pin is consequently made more uniform, the strength of the parts may be reduced, and the friction at slides and journals is lessened. The advantage in this respect is obviously much greater when the cylinders are placed side by side, instead of tandem, and work on cranks at right angles. As a set-off to its advantage in giving a more uniform effort, the compound engine has the drawback of requiring more working parts than a simple engine with one cylinder. But in many instances—as in marine engines—two or more cranks are almost indispensable to give a tolerably uniform effort and to get over the dead points; and the comparison should then be made between a pair of simple cylinders and a pair of compounded cylinders. Another point in favour of the compound engine is that, although the whole ratio of expansion is great, there need not be a very early cut-off in either cylinder; hence the common slide-valve, which is unsuited to give an early cut-off, may be used in place of a more complex arrangement. The mechanical advantage of the compound engine has long been recognized, and had much to do with its adoption in the early days of high-pressure steam. Its subsequent development has been due in part to this, and in part to the thermodynamic advantage which has been discussed above.

59. *Ratio of Cylinder Volumes.*—In a two-cylinder compound engine, using steam at 80 to 100 lb pressure, the large cylinder has 3 or 4 times the volume of the small cylinder. In triple engines the pressure is rarely less than 150 lb; the low-pressure cylinder has generally 6 or 7 times, and the intermediate cylinder $2\frac{1}{2}$ to $2\frac{3}{4}$ times the volume of the high-pressure cylinder. In naval practice the ratios are about $1 : 2\frac{1}{4} : 5$ for a pressure of 160 lb and $1 : 2{\cdot}6 : 7$ for a pressure of 250 lb. In the mercantile marine the engines are normally working at full power, whereas in the navy most of the working is at greatly reduced powers, the cruising speed requiring very much less than the full output. Consequently, for the same boiler pressure, the cylinder ratio is made less in war-ships to adapt the engines for economical working under cruising conditions.

60. *The Distribution of Steam.*—In early steam engines the distribution of steam was effected by means of conical valves, worked by tappets from a rod which hung from the beam. The slide-valve, the invention of which in the form now known as the long **D**-slide

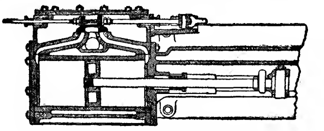

FIG. 18.—Horizontal Section through Cylinder and Valve-chest: showing Slide-valve.

is credited to Murdock, an assistant of Watt, came into general use with the introduction of locomotives, and is now employed, in one or other of many forms, in the great majority of engines.

The common slide-valve is illustrated in fig. 18, which also shows the cylinder and the ports and passages leading to its ends. The seat, or surface on which the valve slides, is a plane surface formed on or fixed to the side of the cylinder, with three ports or openings which extend across the greater part of the cylinder's width. The central opening is the exhaust port through which the steam escapes; the others, or steam ports, which are narrower, lead to the two ends of the cylinder respectively. The valve is a box-shaped cover which slides over the seat, and the whole is enclosed in a chamber called the valve-chest, to which steam from the boiler is admitted. When the valve moves a sufficient distance to either side of the central position, steam enters one end of the cylinder from the valve-chest and escapes from the other end of the cylinder through the cavity of the valve into the exhaust port. The valve is generally moved by an eccentric on the engine shaft, which is mechanically equivalent to a crank whose radius is equal to the eccentricity, or distance from the centre of the shaft to the centre of the eccentric sheave. The eccentric rod is generally so long that the motion of the valve is sensibly the same as that which it would receive were the rod infinitely long. Thus if a circle (fig. 19) be drawn to represent the path of the eccentric centre during a revolution of the engine, and a perpendicular PM be drawn from any point P on a diameter AB, the distance CM is the displacement of the valve from its middle position at the time when the eccentric centre is at P. AB is the whole travel of the valve.

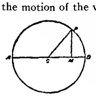

FIG. 19.

61. *Lap and Lead.*—If the valve when in its middle position did not overlap the steam ports (fig. 20), any movement to the right or the left would admit steam, and the admission would continue until the valve had returned to its middle position, or, in other words, for half a revolution of the engine. Such a valve would not serve for expansive working, and as regards the relative position of the crank and eccentric it would have to be set so that its middle position coincided with the extreme position of the piston; in other words,

FIG. 20.—Slide-Valve without Lap.

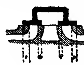

FIG. 21.—Slide-Valve with Lap.

the eccentric radius would make a right angle with the crank. Expansive working, however, becomes possible when we give the valve what is called "lap," by making it project over the edges of the steam ports, as in fig. 21, where *o* is the "outside lap" and *i* is the "inside lap." Admission of steam (to either side) then begins only when the displacement of the valve from its middle position exceeds the amount of the outside lap, and continues only until the valve has returned to the same distance from its middle position. Further, exhaust begins only when the valve has moved past the middle by a distance equal to *i*, and continues until the valve has again returned to a distance *i* from its middle position. Thus on the diagram of the eccentric's travel (fig. 22) we find, by setting off *o* and *i* on the two sides of the centre, the positions *a*, *b*, *c* and *d* of the eccentric radius at which the four events of admission, cut-off, release and compression occur for one side of the piston. As to the other side of the piston, it is only necessary to set off *o* to the right and *i* to the left of the centre, but for the sake of clearness we may confine our attention to one of the two sides. Of the whole revolution, the part from *a* to *b* is the arc of steam admission, from *b* to *c* is the arc of expansion, from *c* to *d* the arc of exhaust, and from *d* to *a* the arc of compression. The relation of these, however, to the piston's motion is still undefined. If the eccentric were set in advance of the crank by an angle equal to AC*a*, the opening of the valve would be coincident with the beginning of the piston's stroke. It is, however, desirable, in order to allow the steam free entry, that the valve be already some way open when the piston stroke begins, and thus the eccentric may be set to have a position C*a'* at the beginning of the stroke. In that case the valve is open at the beginning of the stroke to the extent *mm'*, which is called the "lead." The amount by which the angle between C*a'* (the eccentric) and CA (the crank) exceeds a right angle is called the *angular advance*, this being the angle by which the eccentric is set in advance of the position it would occupy if the primitive arrangement without lap were adopted. The quantities lap, lead and angular advance (θ) are connected by the equation

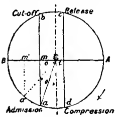

FIG. 22.

$$\text{outside lap} + \text{lead} = \text{half travel} \times \cos\theta.$$

An effect of lead is to cause *preadmission*, that is to say, admission before the end of the back stroke, which, together with the compression of steam left in the cylinder when the exhaust port closes, produces the mechanical effect of "cushioning," to which reference has already been made. To examine the distribution of steam throughout the piston's stroke, we may now draw a circle to represent the path of the crank pin (fig. 23, where the dotted lines

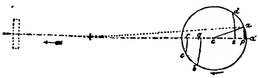

FIG. 23.

have been added to show the assumed configuration of piston, connecting-rod and crank) and transfer to it from the former diagram the angular positions *a*, *b*, *c* and *d* at which the four events occur. To facilitate this transfer the diagrams of eccentric path and of crank-pin path may by a suitable choice of scales be drawn of the same actual size. Then by projecting these points on a diameter which represents the piston's path, by circular arcs drawn with a radius equal to the length of the connecting-rod, we find *p*, the position of the piston at which admission occurs during the back stroke, also *q* and *r*, the position at cut-off and release, during the stroke which takes place in the direction of the arrow, and *s*, the point at which compression begins. It is obviously unnecessary to draw the two circles of figs. 22 and 23 separately; the single diagram (fig. 24) contains the solution of the steam distribution with a slide-valve whose laps, travel and angular advance are known, the same circle serving, on two scales, to show the motion of the crank and of the eccentric.

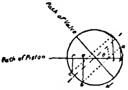

FIG. 24.

Zeuner's Diagram.—The graphic construction most usually employed in slide-valve investigations is the ingenious diagram published by Dr G. Zeuner in the *Civilingenieur* in 1856.[1] On the line AB (fig. 25), which represents the travel of the valve, let a pair of circles (called valve-circles) be drawn, each with diameter equal to the half travel. A radius vector CP, drawn in the direction of the eccentric at any instant, is cut by one of the circles at Q, so that CQ represents the corresponding displacement of the valve from its middle position. That this is so will be seen by drawing PM (as in fig. 19) and joining QB, when it is obvious that CQ = CM, which is the displacement of the valve. The line AB with the circle on it may now be turned back through an angle of $90° + \theta$ (θ being the angular advance), so that the valve-circles take the position shown

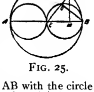

FIG. 25.

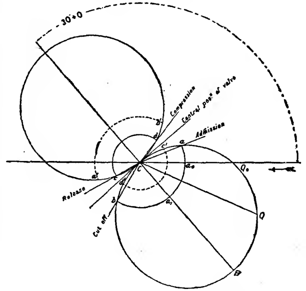

FIG. 26.—Zeuner's Slide-Valve Diagram.

to a larger scale in fig. 26. This makes the direction of CQ (the eccentric) coincide on the paper with the simultaneous direction of

[1] Zeuner, *Treatise on Valve Gears*, trans. by M. Müller (1868).

the crank, and hence to find the displacement of the valve at any position of the crank we have only to draw CQ in fig. 26 parallel to the crank, when CQ represents the displacement of the valve to the scale on which the diameter of each valve circle represents the half-travel of the valve. CQ_0 is the valve displacement at the beginning of the stroke shown by the arrow. Draw circular arcs *ab* and *cd* with C as centre and with radii equal to the outside lap *o* and the inside lap *i* respectively. C*a* is the position of the crank at which pre-admission occurs. The lead is a_0Q_0. The greatest steam opening is a_1B. The cut-off occurs when the crank has the direction C*b*. C*c* is the position of the crank at release, and C*d* marks the end of the exhaust.

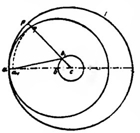

FIG. 27.

63. In this diagram radii drawn from C mark the angular positions of the crank, and their intercepts by the valve circles determine the corresponding displacement of the valve. It remains to find the corresponding displacement of the piston. For this Zeuner employs a supplementary graphic construction, shown in fig. 27. Here *ab* or *a′b′* represents the connecting rod, and *bc* or *b′c* the crank. With centre *c* and radius *ac* a circle *ap* is drawn, and with centre *b* and radius *ab* another circle *aq*. Then for any position of the crank, as *cb′*, the intercept *pq* between the circles is easily seen to be equal to *aa′*, and is therefore the distance by which the piston has moved from its extreme position at the beginning of the stroke. In practice this diagram is combined with that of fig. 26, by drawing both about the same centre and using different scales for valve and piston travel. A radius vector drawn from the centre parallel to the crank in any position then shows the valve's displacement from the valve's middle position by the intercept CQ of fig. 26, and the piston's displacement from the beginning of the piston's motion by the intercept *pq* of fig. 27.

64. In the figures which have been sketched the events refer to the front end of the cylinder, that is, the end nearest to the crank (see fig. 23). To determine the events of steam distribution at the back end, the lap circles shown by dotted lines in fig. 26 must also be drawn, C*a′* being the outside lap for the back end, and C*c′* the inside lap. These laps are not necessarily equal to those at the other end of the valve. From the diagrams it will be seen that, especially with a short connecting-rod, the cut-off and release occur earlier and the compression later at the front than at the back end if the laps are equal, and a more symmetrical steam distribution can be produced by making the inside lap greater and the outside lap less on the side which leads to the front end of the cylinder. On the other hand, an unsymmetrical distribution may be desirable, as in a vertical engine, where the weight of the piston assists the steam during the down-stroke and resists it during the up-stroke, and this may be secured by a suitable inequality in the laps.

65. By varying the ratio of the laps *o* and *i* to the travel of the valve, we produce effects on the steam distribution which are readily traced by means of the diagram. Reduction of travel (which is equivalent to increase of both *o* and *i*) gives later pre-admission, earlier cut-off, later release and earlier compression; the ratios of expansion and of compression are both increased. Increase of angular advance accelerates all the events and causes a slight increase in the ratio of expansion.

66. In designing a slide-valve the breadth of the steam ports in the direction of the valve's motion is determined with reference to the volume of the exhaust steam to be discharged in a given time, the area of the ports being generally such that the mean velocity of the steam during discharge is less than 100 ft. per second. The travel is made great enough to keep the cylinder port fully open during the greater part of the exhaust; for this purpose it is $2\frac{1}{2}$ or 3 times the breadth of the steam port. To facilitate the exit of steam the inside lap is always small, and is often wanting or even *negative*. During admission the steam port is rarely quite uncovered, especially if the outside lap is large and the travel moderate. Large travel has the advantage of giving freer ingress and egress of steam, with more sharply-defined cut-off, compression and release, but this advantage is secured at the cost of more work spent in moving the valve and more wear of the faces. To lessen the necessary travel without reducing the area of steam ports, double-ported valves are often used. An example is shown below in fig. 39.

67. *Reversal of Motion with Slide-Valve.*—The eccentric must stand in advance of the crank by the angle $90° + \theta$, as in fig. 28, where CK is the crank, and CE the corresponding position of the eccentric when the engine is running in the direction of the arrow *a*. To set the engine in gear to run in the opposite direction (*b*) it is only necessary to shift the eccentric into the position CE′, when it will still be $90° + \theta$ in advance of the crank. In the older engines this reversal was effected by temporarily disengaging the eccentric-rod from the valve-rod, working the valve by hand until the crank turned back through an angle equal to ECE′, the eccentric meanwhile remaining at rest, and then re-engaging the gear. The eccentric sheave, instead of being keyed to the shaft, was driven by a stop fixed to the shaft, which abutted on one or other of two shoulders projecting from the sheave. In some modern forms of reversing gear means are provided for turning the eccentric round on the shaft, but the arrangement known as the link-motion is now the most usual gear in locomotive, marine, winding and other engines which require to be often and easily reversed.

FIG. 28.

68. *Link-Motion.*—In the link-motion two eccentrics are used, and the ends of their rods are connected by a link. In Stephenson's link-motion—the earliest and still the most usual form—the link is a slotted bar or pair of bars curved to the same radius as the eccentric rods (fig. 29), and capable of being shifted up or down by a suspension rod. The valve-rod ends in a block which slides within the link, and when the link is placed so that this block is nearly in line with the forward eccentric rod (R. fig. 29) the valve moves in nearly the same way as if it were driven directly by a single eccentric. This is the position of "full forward gear." In "full backward gear," on the other hand, the link is pulled up until the block is in nearly a line with the backward eccentric rod R′. The link-motion thus gives a ready means of reversing the engine—but it does more than this. By setting the link in an intermediate position the valve receives a motion nearly the same as that which would be given by an eccentric of shorter radius and of greater angular advance, and the effect is to give a distribution of steam in which the cut-off is earlier than in full gear, and the expansion and compression are greater. In mid gear the steam distribution is such that scarcely any work is done in the cylinder. The movement of the link is effected by a hand-lever, or by a screw, or (in large engines) by an auxiliary steam engine. A usual arrangement of hand-lever, sketched in fig. 29, has given rise to the phrase "notching up," to describe the setting of the link to give a greater degree of expansion.

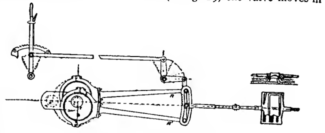

FIG. 29.—Stephenson's Link-Motion.

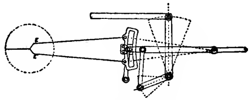

FIG. 30.—Gooch's Link-Motion.

In Gooch's link-motion (fig. 30) the link is not moved up in shifting from forward to backward gear, but a radius rod between the valve-rod and the link (which is curved to suit this radius rod) is raised or lowered—a plan which has the advantage that the lead is the same in all gears. In Allan's motion (fig. 31) the change of gear is effected partly by shifting the link and partly by shifting a radius rod, and the link is straight.

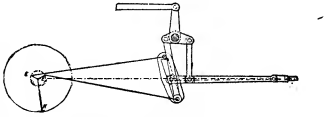

FIG. 31.—Allan's Link-Motion.

69. *Graphic Solution of Link-Motion.*—The movement of a valve driven by a link-motion may be very fully and exactly analysed by drawing with the aid of a template the positions of the centre line of the link corresponding to a number of successive positions of the crank. Thus, in fig. 32, two circular arcs passing through *e* and *e′* are drawn with E and E′ as centres and the eccentric rods are radii. These are loci of two known points of the link, and a third locus is the circle *a* in which the point of suspension must lie. By placing on the paper a template of the link, with these three points marked

on it, the position of the link is readily found, and by repeating the process for other positions of the eccentrics a diagram of positions (fig. 32) is drawn for the assigned state of the gear. A line AB drawn across this diagram in the path of the valve's travel determines the displacements of the valve, and enables the oval diagram to be drawn, which is shown to a larger scale in another part of fig. 32. The example refers to Stephenson's link-motion in nearly full forward gear; with obvious modification the same method may be used in the analysis of Gooch's or Allan's motion. The same

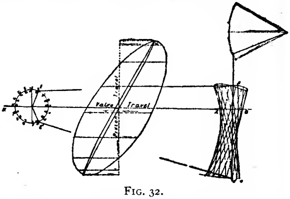

FIG. 32.

diagram determines the amount of slotting or sliding motion of the block in the link. In a well-designed gear this sliding is reduced to a minimum for that position of the gear in which the engine runs most usually. In marine engines the suspension-rod is generally connected to the link at the end of the link next the forward eccentric, to reduce this sliding when the engine is in forward gear.

70.—*Radial Gears.*—Many forms of gear for reversing and for varying expansion have been devised with the object of escaping the use of two eccentrics, and in some both eccentrics are dispensed with. Hackworth's gear, the parent of several others, to which the general name of radial gears is applied, has a single eccentric E (fig. 33) opposite the crank, with an eccentric-rod EQ, whose mean position is perpendicular to the travel of the valve. The rod ends in a block Q, which slides on a fixed inclined guide-bar or link, and the valve-rod receives its motion through a connecting rod from an intermediate point P of the eccentric-rod, the locus of which is an ellipse. To reverse the gear the guide-bar is tilted over to the position shown by the dotted lines, and intermediate inclinations give various degrees of expansion without altering the lead. The steam distribution is quite satisfactory, but an objection to the gear is the wear of the sliding-block and guide. In Bremme's or Marshall's form this objection is obviated with some loss of symmetry in the valve's motion by constraining the motion of the point Q, not by a sliding-guide, but a suspension-link, which makes the path of Q a circular arc instead of a straight line; to reverse the gear the centre of suspension R of this link is thrown over to the position R′ (fig. 34). In the example sketched P is beyond Q, but P may be between Q and the crank (as in fig. 33), in which case the eccentric is set at 180° from the crank. This gear has been applied in a number of marine engines. In Joy's gear, which is extensively used in locomotives, no eccentric is required; and the rod corresponding to the eccentric rod in Hackworth's gear receives its motion from a point in the connecting rod by the linkage shown in fig. 35, and is either suspended, as in Marshall's form, by a rod whose suspension centre R is thrown over to reverse the motion, or constrained, as in Hackworth's, by a slot-guide whose inclination is reversed. Fig. 36 shows Joy's gear as applied to a locomotive. A slot-guide E is used, and it is curved to allow for the obliquity of the valve connecting-rod AE. C is the crank-pin, B the piston path and D a fixed centre.

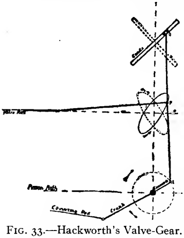

FIG. 33.—Hackworth's Valve-Gear.

A form of radial gear very largely used in locomotives, especially on the continent of Europe, is the Walschaert or Heusinger-Waldegg gear, in which the valve receives its motion in part from the piston cross-head through a reducing lever, and in part from a single eccentric set at right angles to the crank, which actuates a rocking link. Reversing is effected by shifting a sliding block along this rocking link from one side to the other of the centre on which it rocks.

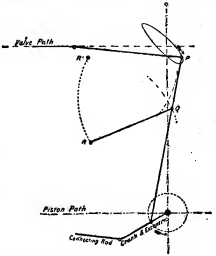

FIG. 34.—Bremme's or Marshall's Valve-Gear.

71. *Separate Expansion-Valves.*—When the distribution of steam is effected by the slide-valve alone the arc of the crank's motion during which compression occurs is equal to the arc during which expansion occurs, and for this reason the slide-valve would give an

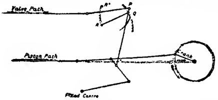

FIG. 35.—Diagram of Joy's Valve-Gear.

excessive amount of compression if it were made to cut off the supply of steam earlier than about half-stroke. Hence, where an early cut-off is wanted it is necessary either to use an entirely different means of regulating the distribution of steam, or to supplement the

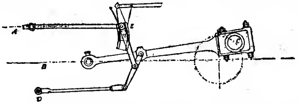

FIG. 36.—Joy's Gear as applied to a Locomotive.

slide-valve by another valve—called an expansion-valve, usually driven by a separate eccentric—whose function is to effect the cut-off, the other events being determined as usual by the slide-valve. Such expansion-valves belong generally to one or other of two types. In one the expansion-valve cuts off the supply of steam to the chest in which the main valve works.

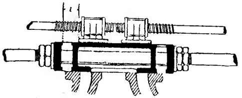

FIG. 37.—Expansion-Valve on back of Main Slide-Valve.

In the other the expansion-valve slides on the back of the main slide-valve, which is provided with through ports which the expansion-valve opens and closes Fig. 37 shows one form of this type. Here the resultant relative motion of the expansion-valve and main-valve has to be considered. If r_a and r (fig. 38) are the eccentrics working the main and expansion valves respectively, then CR drawn equal and parallel to ME is the *resultant* eccentric which determines the motion of the expansion-valve relatively to the main-valve. Cut-off occurs at Q, when the shaft has turned through an

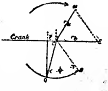

FIG. 38.

angle ϕ, which brings the resultant eccentric into the direction CQ and makes the relative displacement of the two valves equal to the distance l.

Expansion-valves furnish a convenient means of *varying* the expansion, which may be done by altering their lap, travel or angular advance. Alteration of lap, or rather of the distance l in the figures, is often effected by having the expansion-valve in two parts (as in fig. 37) and holding them on one rod by right- and left-handed screws respectively; by turning the valve-rod the parts are made to approach or recede from each other. In large valves the adjustment is more conveniently made by varying the travel of the valve, which is done by connecting it to its eccentric through a link which serves as a lever of variable length.

72. *Relief Rings.*—To relieve the pressure of the valve on the seat, large slide-valves are generally fitted with a steam-tight ring, which excludes steam from the greater part of the back of the valve. The ring fits steam-tight into a recess in the cover of the steam-chest, and is pressed by springs against the back of the valve, which is planed smooth to slide under the ring. Fig. 39 shows a relief ring of this kind fitted on the back of a large double-ported slide-valve for a marine engine. Another plan is to fit the ring into a recess on the back of the valve, and let it slide on the inside of the steam-chest cover. Steam is thus excluded from the space within the ring, any steam that leaks in being allowed to escape to the condenser (or to the intermediate receiver when the arrangement is fitted to the high-pressure cylinder of a compound engine). A flexible diaphragm has also been used, instead of a recess, to hold the ring.

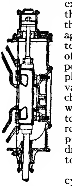

FIG. 39.

73. *Piston Slide-Valve.*—The pressure of valves on cylinder faces is still more completely obviated by making the back of the valve similar to its face, and causing the back to slide in contact with the valve-chest cover, which has recesses corresponding to the cylinder ports. This arrangement is most perfectly carried out in the piston slide-valves now very largely used in the high-pressure cylinders of marine engines. The piston slide-valve may be described as a slide-valve in which the valve face is curved to form a complete cylinder, round whose whole circumference the ports extend. The pistons are packed like ordinary cylinder pistons by metallic rings, and the ports are crossed here and there by diagonal bars to keep the rings from springing out as the valve moves over them. Fig. 40 shows a form of piston valve for the supply of high-pressure steam to a large marine engine. P, P are the cylinder ports.

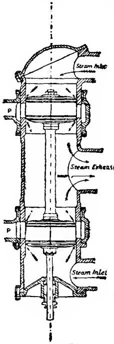

FIG. 40.—Piston Slide-Valve.

74. *Balance Piston.*—Fig. 39 illustrates an arrangement common in all heavy slide-valves whose travel is vertical—the *balance piston*, which is pressed up by steam on its lower side and so equilibrates the weight of the valve, valve-rod and connected parts of the mechanism.

The valve sometimes takes the form of a rocking cylinder. This last kind of sliding motion is very usual in stationary engines fitted with Corliss gear, in which case four distinct rocking slides are commonly employed to effect the steam distribution, one giving admission and one giving exhaust at each end of the cylinder.

75. *Double-Beat Valve.*—In many stationary engines, especially on the continent of Europe, *lift* or *mushroom* valves are used, worked by tappets, cams or eccentrics. Lift-valves are generally of the Cornish or double-beat type (fig. 41), in which equilibrium is secured by the use of two conical faces which open or close together. In Cornish pumping engines, which retain the single action of Watt's early engine, three double-beat valves are used, as steam-valve, equilibrium-valve and exhaust-valve respectively. These are closed by tappets on a rod moving with the beam, but are opened by means of a device called a cataract, which acts as follows: The cataract is a small pump with a weighted plunger, discharging fluid through a stop-cock which can be adjusted by hand when it is desired to alter the speed of the engine. The weighted plunger is raised by a rod from the beam, but is free in its descent, so that it comes down at a rate depending on the extent to which the stop-cock is opened. When it comes down a certain way it opens the steam and exhaust valves, by liberating catches which hold them closed; the "out-door" stroke then begins and admission continues until the steam-valve is closed: this is done directly by the motion of the beam, which also, at a later point in the stroke, closes the exhaust. Then the equilibrium-valve is opened, and the "in-door" stroke takes place, during which the plunger of the cataract is raised. When it is completed, the piston pauses until the cataract causes the steam-valve to open and the next "out-door" stroke begins. By applying a cataract to the equilibrium-valve also, a pause is introduced at the end of the "out-door" stroke. Pauses have the advantage of giving the pump time to fill and of allowing the pump-valves to settle in their seats without shock.

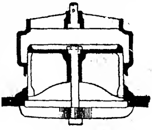

FIG. 41.—Double-Beat Lift Valve.

76. *Methods of Regulating.*—To make an engine run steadily an almost continuous process of adjustment must go on, by which the amount of work done by the steam in the cylinder is adapted to the amount of external work demanded of the engine. Even in cases where the demand for work is sensibly uniform, fluctuations in boiler-pressure still make regulation necessary. Generally the process of government aims at regularity of speed; occasionally, however, it is some other condition of running that is maintained constant, as when an engine driving a dynamo-electric machine is governed by an electric regulator to give a constant difference of potential between the brushes.

The ordinary methods of regulating are either (*a*) to alter the pressure at which steam is admitted by opening or closing more or less a throttle-valve between the boiler and the engine, or (*b*) to alter the volume of steam admitted to the cylinder by varying the point of cut-off. The former plan was introduced by Watt and is still common, especially in small engines. The second plan of regulating is generally preferred, especially when the engine is subject to large variations of load. Within certain limits regulation by either plan can be effected by hand, but for the finer adjustment of speed some form of automatic governor is necessary. Speed governors are commonly of the *centrifugal* type: a pair of masses revolving about a spindle which is driven by the engine are kept from flying out by a certain controlling force. When an increase of speed occurs this controlling force is no longer able to keep the masses revolving in their former path; they move out until the controlling force is sufficiently increased, and in moving out they act on the regulator of the engine, which may be a throttle-valve or some form of automatic expansion gear. In the conical pendulum governor of Watt (fig. 42) the revolving masses are balls attached to a vertical spindle by links, and the controlling force is furnished by the weight of the balls, which, in receding from the spindle, are obliged to rise. When the speed exceeds or falls short of its normal value they move out or in, and so raise or lower a collar c which is in connexion by a lever with the throttle-valve.

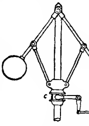

FIG. 42.—Watt's Governor.

77. *Loaded Governor.*—In a modified form, known as the loaded governor, a supplementary controlling force is given by placing a weight on the sliding collar (fig. 43). This is equivalent to increasing the *weight* of the balls without altering their *mass*. In other governors the controlling force is wholly or partly produced by springs. The use of springs to provide controlling force allows the axis of rotation to be horizontal, and governors of this class are frequently attached directly to the horizontal shaft in high-speed engines.

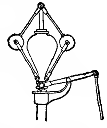

FIG. 43.—Loaded Governor.

78. *Equilibrium of Governor.*—In whatever way the revolving masses are controlled, the controlling force may be treated as a force F acting on each ball in the direction of the radius towards the axis of revolution. Then, if M be the mass of the ball, n the number of revolutions per second and r the radius of the ball's path, the governor will revolve in equilibrium when $F = 4\pi^2 n^2 r M$ (in absolute units), or

$$n = \frac{1}{2\pi}\sqrt{\frac{F}{Mr}}.$$

In order that the configuration of the governor should be stable, F must increase more rapidly than r, as the balls move outwards. It is obvious that no *stable* governor maintains a strictly constant speed in the engine which it controls. If the boiler pressure or the demand for work is changed, a certain amount of permanent displacement of the balls is necessary to alter the steam-supply, and the balls can retain their displaced position only by virtue of a permanent change in the speed. The maximum range of speed depends on that amount of change of n which suffices to alter the configuration of the governor from the position which gives no steam-supply to the position which gives full steam-supply, and the governor is said to be sensitive if this range is a small fraction of n.

To find the configuration which the governor will assume at any particular speed, or the speed corresponding to a particular configuration, it is only necessary to determine the whole controlling force F per ball acting along the radius towards the axis for various values of r. Let a curve ab (fig. 44) be drawn showing the relation of F to r. At any assigned value of r set up an ordinate $QC = 4\pi^2n^2rM$. Join OC. The point c, in which OC cuts the curve, determines the value of r at which the balls will revolve at the assigned speed n. Or, if that is given, and the value of n is to be found, the line Oc produced will determine C, and then $n^2 = QC/4\pi^2rM$. The sensibility of the governor is determined by taking points a and b corresponding to full steam and no steam respectively, and drawing lines through them to determine the corresponding values of QA and QB. When the frictional resistance f is known, an additional pair of curves drawn above and below ab, with ordinates $F + f$ and $F - f$ respectively, serve to show the additional variations in speed which are caused by friction. The governor is stable throughout its whole range when the curve ab has a steeper gradient than any line drawn from O to meet it.

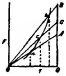

FIG. 44.

79. *Isochronism*.—If, when the balls are displaced, the controlling force F changes proportionally to the radius r, the speed is constant. In other words, the equilibrium of the governor is then neutral; it can revolve in equilibrium at one, and only at one, speed. At this speed it assumes, indifferently, any one of its possible configurations. The slightest variation of speed drives it to the extremity of its range; hence its sensibility is indefinitely great. Such a governor is called *isochronous*. Where springs furnish the controlling force, an approach to isochronism can be secured by adjusting the initial tension of the springs, and this forms a convenient means of regulating the sensibility.

But in practice no governor can be absolutely isochronous. It is indispensable to leave a small margin of stability for the sake of preventing violent change in the supply of steam, especially when there is much frictional resistance to be overcome by the governor, or where the influence of the governor takes much time to be felt by the engine. An over-sensitive governor is liable to fall into a state of oscillation called *hunting*. When an alteration of speed begins to be felt, however readily the governor alters its form, the engine's response is more or less delayed. If the governor acts by closing a throttle-valve, the engine has still a capacious valve-chest on which to draw for steam. If it acts by changing the cut-off, its opportunity is passed if the cut-off has already occurred, and the control only begins with the next stroke.

When the demand for power suddenly falls, the speed rises so much as to force the governor into a position of over-control, such that the supply of steam is no longer adequate to meet even the reduced demand for power. Then the speed slackens, and the same kind of excessive regulation is repeated in the opposite direction. A state of forced oscillation is consequently set up. The effect is aggravated by the momentum which the governor balls acqure in being displaced. Hunting is to be avoided by giving the governor a fair degree of stability, by reducing as far as possible the static frictional resistances, and by introducing a *viscous* resistance to the displacement of the governor, which prevents the displacement from occurring too suddenly, without affecting the ultimate position of equilibrium. For this purpose many governors are furnished with a *dash-pot*, which is a hydraulic or pneumatic brake, consisting of a piston connected to the governor, working loosely in a cylinder which is filled with oil or with air.

80. *Regulation by the Governor of the Steam-Supply: Throttle-Valve.*—The throttle-valve, as introduced by Watt, was originally a disk turning on a transverse axis across the centre of the steam-pipe. It is now usually a double-beat valve or a piston-valve. When regulation is effected by varying the cut-off, and an expansion-valve of the slide-valve type is used, the governor generally acts by changing the travel of the valve. In other forms of automatic expansion-gear the lap of the valve is altered; in others the governor acts by shifting the expansion-valve eccentric round on its shaft, and so changing its angular advance.

81. *Trip-Gear.*—In large stationary engines the most usual plan of automatically regulating the expansion is to employ some form of trip-gear, the earliest type of which was introduced in 1849 by G. H. Corliss (1817–1888), of Providence, U.S.A. In the Corliss system the valves which admit steam are distinct from the exhaust-valves. The latter are opened and closed by a reciprocating piece which takes its motion from an eccentric. The former are opened by a reciprocating piece, but are closed by springing back when released by a trip- or trigger-action. The trip occurs earlier or later in the piston's stroke according to the position of the governor. The admission-valve is opened by the reciprocating piece with equal rapidity whether the cut-off is going to be early or late. It remains wide open during the admission, and then, when the trip-action comes into play, it closes suddenly. The indicator diagram of a Corliss engine consequently has a nearly horizontal admission-line and a sharply defined cut-off. Generally the valves of Corliss engines are cylindrical plates turning in hollow cylindrical seats which extend across the width of the cylinder. Often, however, the admission-valves in trip-gear engines are of the disk or double-beat type, and spring into their seats when

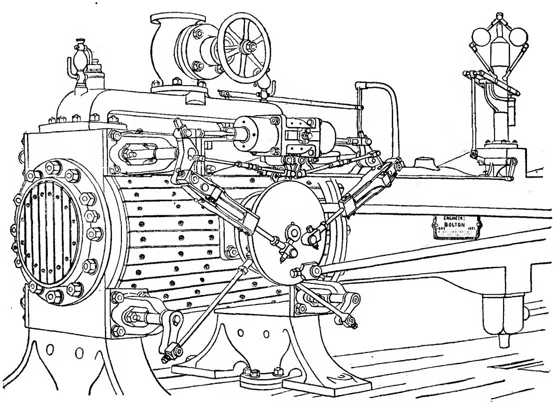

FIG. 45.—Corliss Engine, with Spencer Inglis Trip-Gear.

the trip-gear acts. Messrs Sulzer have developed this type with much success. Many forms of trip-gear have been invented by Corliss himself and by others. One of these, the Spencer Inglis trip-gear, by Messrs Hick, Hargreaves & Co., is shown in figs. 45 and 46. A wrist-plate A, which turns on a pin on the outside of the cylinder, receives a motion of oscillation from an eccentric. It opens the cylindrical rocking-valve B by pulling the link C, which consists of two parts, connected to each other by a pair of spring clips *a*, *a*. Between the clips there is a rocking-cam *b*, and as the link is pulled down this cam places itself more and more athwart the link, until at a certain point it forces the clips open. Then the upper part of the link springs back and allows the valve B to close by the action of a spring in the dash-pot D. When the wrist-plate makes its return stroke the clips re-engage the upper portion of the link C, and things are ready for the next stroke. The rocking-cam *b* has its position controlled by the governor through the link E in

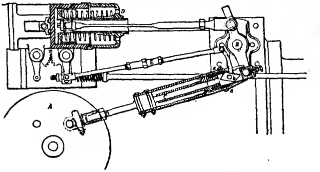

FIG. 46.—Corliss Valve-Gear, Spencer Inglis form.

such a way that when the speed of the engine increases it stands more athwart the link C, and therefore causes the clips to be released at an earlier point in the stroke. A precisely similar arrangement governs the admission of steam to the other end of the cylinder. The exhaust-valves are situated at the bottom of the cylinder, and receive an oscillating motion from a separate wrist-plate, behind A.

82. *Use of Flywheel.*—Besides those variations of speed which occur from stroke to stroke, which it is the business of the governor to check, there are variations within each single stroke due to the varying rate at which work is done on the crank-shaft during its revolution. To limit these is the function of the flywheel, which acts by forming a reservoir of energy to be drawn upon during those parts of the revolution in which the work done on the shaft is less than the work done by the shaft, and to take up the surplus in those parts of the revolution in which the work done on the shaft is greater than the work done by it. This alternate storing and restoring of energy is accomplished by slight fluctuations of speed, whose range depends on the ratio which the alternate excess and defect of energy bears to the whole stock the flywheel holds in virtue of its motion. The effect of the flywheel may be studied by drawing a diagram of crank-effort, which shows the work done on the crank in the same way that the indicator diagram shows the work done on the piston. The same diagram serves another useful purpose in determining the twisting and bending stress in the crank.

The diagram of crank-effort is drawn by representing, in rectangular co-ordinates, the relation between the moment which the connecting-rod exerts to turn the crank and the angle turned through by the crank. The moment exerted to turn the crank is readily found when the direction and magnitude of the thrust exerted by the connecting-rod on the crank-pin is known for successive points in the revolution.

83. *Influence of the Inertia of the Reciprocating Masses.*—This thrust depends not only on the resultant pressure of the steam on the piston but also on the inertia of the reciprocating masses. The mass of the piston, piston-rod, cross-head, and to some extent that of the connecting-rod also, has to be started and stopped in each half revolution, and in high-speed engines the forces concerned in this action are so large as to affect most materially not only the distribution of crank-effort but also the stresses which the various parts have to be proportioned to bear. The calculation of the stresses due to inertia in high-speed engines consequently forms an essential part of engine design. Taking M to represent the whole reciprocating mass, and *a* its acceleration at any instant in the direction of the piston's motion, the force required to produce this acceleration is Ma/g, and this quantity has to be deducted from the resultant pressure of the steam in finding the effective thrust. The effect is to reduce the effective thrust at the beginning of the stroke and to increase it at the end. The greatest acceleration *a* occurs in the extreme position of the piston, most distant from the crank-shaft centre, and its value there is $4\pi^2n^2r(1 + r/l)$ where r is the radius of the crank, l the length of the connecting-rod and n the number of turns per second. When the piston is in the other extreme position, nearest to the shaft, the value of a is $4\pi^2n^2r(1 - r/l)$. The exact calculation of inertia effects for the connecting-rod is complicated, but its influence on the thrust is approximately found by treating the mass of the rod as divided into two parts, one of which moves with the cross-head and is therefore an addition to the reciprocating system, while the other moves with the crank-pin and is therefore an addition to the revolving system. The mass may be divided for this purpose into parts which are inversely proportional to the distances of the centre of gravity from the cross-head and crank-pin respectively. By combining diagrams of the steam thrust and of the forces due to inertia a diagram is obtained showing the true thrust throughout the stroke. Fig. 47 gives an example: there the line *ab* is drawn to show the inertia forces for an engine in which the connecting-rod has $3\frac{1}{2}$ times the length of the crank. The straight line *cd* shows what the inertia force would be if the connecting-rod were treated as being so long that the deviation from simple-harmonic motion might be neglected.

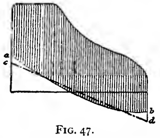

FIG. 47.

The inertia of the reciprocating parts imposes a limit on the lightness of engines of the piston and cylinder type. The proportion of weight to power is reduced by increasing mean piston speeds, but this process cannot be carried beyond a point at which the forces due to inertia become so great as to produce unsafely high alternating stresses in the piston-rods and other parts. In some torpedo-boat destroyers, where the reduction of weight has been carried as far as is practicable, the mean piston speed approaches 1200 ft. per minute with nearly 400 revolutions per minute and an 18-in. stroke. These engines develop 6000 h.p., and the weight of engines and boiler together is only 50 ℔ per indicated h.p. Such a figure is, however, to be regarded as exceptional; weights of 150 to 200 ℔ per h.p. are more usual even in conditions like those of high-speed cruisers where saving of weight is specially desirable.

84. *Balancing.*—Another aspect in which the inertia of the reciprocating parts is important is in regard to the balancing of the engine as a whole. Any forces required to accelerate the piston and its attached parts produce reaction on the frame and bed-plate of the engine, which will set up vibrational disturbances in the foundations and ground or the supporting structure. The object of balancing is to group the masses in such a manner that their inertia effects more or less neutralize one another. This is especially important in marine engines, where massive foundations are absent and where it may happen that the periodic impulses due to want of balance find some portion of the hull free to respond synchronously with vibrations so violent as to be inconvenient and even dangerous. Even in land engines a want of balance causes enough vibration to constitute a serious nuisance in the neighbourhood.

85. In considering the question of balance, the system of eccentrically revolving masses and the system of reciprocating masses have to be considered separately. A reciprocating mass such as a piston cannot be balanced by the use of revolving masses, for the forces which are due to the inertia of the piston necessarily act along the line of its stroke, while those due to revolving masses are continually changing their direction. The inertia of each connecting-rod may be approximately treated by resolving its mass into two constituents, one of which moves with the crank-pin, and is therefore an addition to the revolving system, while the other moves with the cross-head, and is therefore an addition to the reciprocating system. The mass of the rod may be divided for this purpose into parts which are inversely proportional to the distances of its centre of gravity from the crank-pin and the cross-head respectively. Let M_1, M_2, M_3, &c., represent the various revolving masses r_1, r_2, r_3, &c., their effective radii of rotation, and a_1, a_2, a_3, &c., their distances from any assumed plane of reference taken perpendicular to the shaft. Then the conditions necessary for balance amongst them are that the vector sum of $M\,r$ shall vanish, and also that the vector sum of $M\,a\,r$ shall vanish, this latter quantity being the resultant of the moments of the centrifugal forces with respect to the plane of reference. In a four-crank engine there is no serious difficulty in arranging the revolving masses in such a manner that these conditions shall be satisfied, so far as those masses are concerned. The problem, as Professor W. E. Dalby has shown, lends itself readily to graphical treatment (see his treatise on *Balancing of Engines*). With respect to the reciprocating masses, a first approximation towards balance is attained by satisfying the conditions which would secure balance if the motions were simply harmonic. These conditions are identical with those which have just been stated for the revolving masses, when r is interpreted as the semi-amplitude of the harmonic motion. When the conditions in question are satisfied, the only remaining source of disturbance is that which comes from the fact that the reciprocating masses are connected to the cranks by rods of finite length; in other words, that the motions are not simply harmonic. For this reason the force required to accelerate each piston is greater when the piston is at the end of the stroke farthest from the shaft than when it is at the other end, and consequently the balance, which would be perfect if the connecting-rods were

indefinitely long, is disturbed by the presence of forces which vary periodically with a frequency twice that of the rotation. When three cranks, 120° apart, are employed, it will be found that the effect of the shortness of the connecting-rods in causing forces to act in the line of the stroke is reduced to a couple tending to tilt the engine in a fore and aft direction, which may in its turn be balanced by using a second set of three cranks on the same shaft, the second set being so arranged that the couple to which it gives rise neutralizes the couple due to the first set. A six-crank engine may be arranged in this way to secure an extremely close approximation to perfect balance, and the same state of balance can be secured when the number of cranks is reduced to five.

86. The most usual arrangement adopted in marine engines, when questions of balance are taken into account, is to have four cranks, and consequently four sets of reciprocating masses. In the "Yarrow-Schlick-Tweedy" system of balancing engines four cranks are employed, and by adjusting the relative weights of the four pistons, as well as their distances apart, and by selecting suitable angles for the relative positions of the cranks (differing somewhat from 90°), a close approximation to complete balance is obtained. In triple expansion this arrangement is readily applied when two low-pressure cylinders are used instead of one, the steam from the intermediate cylinder being divided between them, and it is also of course applicable to quadruple expansion engines.

87. In this connexion mention may be made of a type of engine which has been used in various electric power stations, especially in America, in which a revolving mass might be employed to balance completely the inertia effects of two pistons. This is a compound engine in which the cylinders stand at right angles to one another, one being horizontal and the other vertical. If the piston masses were made equal it is clear that the inertia effect of a revolving mass could be resolved into two components which would balance both. It does not appear, however, that advantage has been taken of this property in the design of actual engines of this type. In the London County Council power station at Greenwich, where the engines are of this class, the unbalanced effects of inertia are so considerable as to affect the instruments at the Observatory half a mile away. One of the conspicuous merits of the steam turbine is that it avoids the use of reciprocating parts and so escapes the inconveniences and limitations to which the inertia of reciprocating parts gives rise.

88. *Types of Engine.*—In classifying engines with regard to their general arrangement of parts and mode of working, account has to be taken of a considerable number of independent characteristics. We have first a general division into *condensing* and *non-condensing* engines, with a subdivision of the condensing class into those which act by surface condensation and those which use injection. Next there is the division into *compound* and *non-compound*, with a further classification of the former as double-, triple- or quadruple-expansion engines. Again, engines may be classed as *single* or *double-acting*, according as the steam acts on one or alternately on both sides of the piston. Again, a few engines—such as steam hammers and certain kinds of steam pumps—are *non-rotative*, that is to say, the reciprocating motion of the piston does work simply on a reciprocating piece; but generally an engine does work on a continuously revolving shaft, and is termed *rotative*. In most cases the crank-pin of the revolving shaft is connected directly with the piston-rod by a connecting-rod, and the engine is then said to be *direct-acting*; in other cases, of which the ordinary beam engine is the most important example, a lever is interposed between the piston and the connecting-rod. The same distinction applies to non-rotative pumping engines, in some of which the piston acts directly on the pump-rod, while in others it acts through a beam. The position of the cylinder is another element of classification, giving *horizontal*, *vertical* and *inclined cylinder* engines. Many vertical engines are further distinguished as belonging to the *inverted cylinder* class; that is to say, the cylinder is above the connecting-rod and crank. In *oscillating cylinder* engines the connecting-rod is dispensed with; the piston-rod works on the crank-pin, and the cylinder oscillates on trunnions to allow the piston-rod to follow the crank-pin round its circular path. In *trunk* engines the piston rod is dispensed with; the connecting-rod extends as far as the piston, to which it is jointed, and a trunk or tubular extension of the piston, through the cylinder cover, gives room for the rod to oscillate. In *rotary* engines there is no piston in the ordinary sense; the steam does work on a revolving piece, and the necessity is thus avoided of afterwards converting reciprocating into rotary motion. *Steam turbines* may, in one sense, be regarded as an extreme development of the rotary type; but they are distinct from all other steam engines in this that their action depends on the kinetic energy of the steam.

89. *Beam Engines.*—In the single-acting atmospheric engine of Newcomen the beam was a necessary feature; the use of water-packing for the piston required that the piston should move down in the working stroke, and a beam was needed to let the counterpoise pull the piston up. Watt's improvements made the beam no longer necessary; and in one of the forms he designed it was discarded—namely, in the form of pumping engine known as the Bull engine, in which a vertical inverted cylinder stands over and acts directly on the pump-rod. But the beam type was generally retained by Watt, and for many years it remained a favourite with builders of engines of the larger class. The beam formed a convenient driver for pump-rods and valve-rods; and the parallel motion (*q.v.*) invented by Watt as a means of guiding the piston-rod, which could easily be applied to a beam engine, was, in the early days of engine-building, an easier thing to construct than the plane surfaces which are the natural guides of the piston-rod in a direct-acting engine. In modern practice the direct-acting type has to a very great extent displaced the beam type. For mill-driving and the general purposes of a rotative engine the beam type is now rarely chosen. In pumping engines it is somewhat more common, but even there the direct-acting forms are generally preferred.

90. *Direct-Acting Engines.*—Of direct-acting engines the horizontal type has in general the advantage of greater accessibility, but the vertical economizes floor space. In small forms the engine is generally self-contained, that is to say, a single frame or bedplate carries all the parts including the main bearings in which the crank-shaft with its flywheel turns. The frame often takes what is called a girder shape, which brings a portion of it into a favourable position for taking the thrust between the cylinder and the crank-shaft bearings and allows two surfaces to be formed on the frame to serve as guides for the cross-head. When a condenser is used with a horizontal engine it is usually placed behind the cylinder, and the air-pump, which is within the condenser, has a horizontal plunger or piston on a "tail-rod" or continuation of the main piston-rod through the back cover of the cylinder. In large horizontal engines the condenser generally stands in a well below, and its pump, which is vertical, is driven by means of a bell-crank lever attached by a link to the engine cross-head.

91. *Coupled Engines.*—When uniformity of driving effort or the absence of dead points is important, two independent cylinders often work on the same shaft by cranks at right angles to each other. Such engines, which are called "coupled," can start readily from any position; the ordinary locomotive engine is an example. Winding engines for mines and collieries, in which ease of starting, stopping and reversing is essential, are very generally made by coupling a pair of cylinders on opposite sides of the winding drum with link motions as the means of operating the valves.

92. *Compound Engines, Coupled or Tandem.*—Large direct-acting engines are usually compounded either by having a high- and a low-pressure cylinder side by side, with cranks at right angles, or by putting one cylinder behind the other with the axes of both in the same line. The latter is called the *tandem* arrangement. In a tandem engine, since the pistons agree in phase, the steam may expand directly from the small into the large cylinder. But the connecting-pipe and steam chest form a receiver of considerable size, and to avoid loss by "drop" the supply of steam to the large cylinder is cut off long before the end of the stroke. For mill engines the compound tandem and compound coupled types of engine are the most usual. The high-pressure cylinder is very generally fitted with Corliss or other trip-gear.

93. *Jet and Surface Condensation.*—In land engines using condensation the jet form of condenser is common, but surface condensation is resorted to when the available water-supply is unsuited for boiler feed. When there is no large supply of condensing water a very fair vacuum can be obtained by using

an *evaporative condenser*, consisting of a stack of pipes into which the exhaust steam is admitted and over which a small amount of cooling water is allowed to drip. This water is evaporated by the heat which is extracted in condensing the steam within. Such a condenser is placed in the open, generally on a roof where the air has free access. The amount of water it uses need not exceed the amount of steam that is condensed, and is therefore a very small fraction of the amount required in a jet or surface condenser.

94. *High-Speed Direct-Acting Engines.*—Prior to the advent of the steam turbine the demand for engines suitable for driving electric generators without the intervention of a belt led to the introduction of various forms of direct-acting engine adapted to run at a high speed. Some of these were *single acting*, steam being admitted to one side of the piston only, generally the back, with the result that the rods could be kept in a state of thrust throughout the revolution, and alternations of stress in them and at the joints thereby avoided, together with the knocking and wear of the bearing brasses which it is apt to cause. To secure, however, that the connecting-rod should always push and never pull against the crank-pin there had to be much cushioning during the out stroke on account of the fact that from about the middle of that stroke to the end the reciprocating mass was being retarded. In engines designed by P. W. Willans, which were highly successful examples of this class, the cushioning was provided by means of a supplementary piston which compressed air during the out stroke; the energy which the reciprocating masses had to part with in losing their motion during the second half of the out stroke was stored in this air and was restored in the succeeding down stroke.

Willans obtained compound or triple expansion by mounting two or three cylinders in tandem in a vertical line, with the air-compressing piston below them in the form of a trunk which served also as a guide for the cross-head. The piston-rod was hollow and within it there was a valve rod carrying piston valves for the admission and release of the steam. The valve rod was worked by an eccentric on the crank-pin which gave it the proper relative motion with respect to the hollow piston within which it works. The engine was entirely enclosed in a casing the bottom of which formed an oil bath in which the cranks splashed to ensure ample lubrication. These engines for a time had much vogue and gave good results. Many of them are in use in electric light stations and elsewhere, but the tendency now is to use turbines for this class of work, and even in cases where reciprocating engines are preferred they are now more usually of the double-acting type, which has the advantage of giving a greater output of power for the same weight.

95. *Double-Acting High-Speed Engines.*—Of double-acting high-speed engines an interesting form is that of Messrs Belliss and Morcom, the chief distinctive feature of which is the use of forced lubrication at the pin joints and shaft bearings. In a double-acting engine, where the thrust acts alternately on one and the other side of the crank-pins and cross-head pins, high frequency of stroke tends to produce much knocking and wear unless the brasses are very closely adjusted, and in that case the pins are liable to get hot, and to "seize" by expanding sufficiently to fill the small clearance. This difficulty, which exists when lubrication is carried out in the ordinary way, is overcome in the Belliss engine by feeding the bearings with a continuous supply of oil, which is pumped in under a pressure of about 15 lb per sq. in. The presence of a film of oil is thereby continuously secured, and knocking is prevented although the brasses are not set very close. Notable examples in which double action is combined with a relatively high frequency of stroke are found in naval engineering practice, especially in the engines of high-speed cruisers and torpedo-boat destroyers. As a rule these engines employ triple expansion with four cranks and four cylinders, the third stage of the expansion being performed in two cylinders, which divide the steam between them. But in this field also the steam turbine is rapidly displacing the reciprocating type.

96. *Pumping Engines.*—In engines for pumping or for blowing air it is not essential to drive a revolving shaft, and in many forms the reciprocating motion of the steam piston is applied directly or through a beam to produce the reciprocating motion of the pump-piston or plunger. On the other hand, pumping engines are frequently made rotative for the sake of adding a flywheel.

Fig. 48 shows a compound inverted vertical pumping engine of the non-rotative class by Messrs Hathorn, Davey & Co. Steam is distributed through lift valves, and the distribution

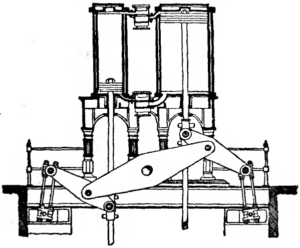

FIG. 48.—Vertical Non-Rotative Pumping Engine.

of steam is controlled by means of a cataract, which makes the pistons pause at the end of each stroke. The pistons are in line with two pump-rods, and are coupled by an inverted beam which gives guidance to the cross-heads by means of an approximate straight-line motion. Engines of this kind, like the old Cornish pump, are able to work expansively against a uniform resistance without a flywheel in consequence of the great inertia of the reciprocating pieces which include long massive pump-rods. Notwithstanding the low frequency of the strokes, enough energy is stored in the moving rods to counterbalance the inequalities of steam thrust, and the rate of acceleration of the system adjusts itself to give, at the plunger end, the nearly uniform effort which the pump requires. In other words, the motion, instead of being almost simple harmonic as it is in rotative engines, is such that the form of the inertia curve when drawn as in fig. 47 is nearly the same as that of the steam curve, with the result that the distance between the two, which represents the net effort on the pump-plunger, is nearly constant. The massive pump-rods act in such a way as to form a reciprocating equivalent of a flywheel.

97. It is, however, only to deep well pumping that this applies, and a very numerous class of direct-acting steam pumps have too little mass in their reciprocating parts to allow such an adjustment to take place. A familiar example is the small donkey pump used for feeding boilers, in which the steam-piston and pump-plunger are on one and the same rod. In some of these pumps a rotative element is introduced, partly to secure steadiness of working and partly for convenience in working the valves. But many pumps of this class are entirely non-rotative, and in such cases the steam is generally admitted throughout the stroke without expansion. In some of them the valve is worked by tappets from the piston-rod. In the Blake steam pump a tappet worked by the piston as it reaches each end of its stroke throws over an auxiliary steam-valve, which admits steam to one or other side of an auxiliary piston carrying the main slide-valve.

98. *Worthington Engines.*—In the Worthington pumping engine two steam cylinders are placed side by side, each working its own pump-piston. The piston-rod of each is connected by a short link to a swinging bar, which actuates the slide-valve of the other steam cylinder. In this way one piston begins its stroke when the motion of the other is about to cease, and a

smooth and continuous action is secured. These engines have been extensively applied, on a large scale, to raise water for the supply of towns and to force oil through "pipe-lines" in the United States. In the larger sizes they are made compound, each high-pressure cylinder having a low-pressure cylinder tandem with it on the same rod. To allow of expansive working a device is added which compensates for the inequality of effort resulting from an early cut-off. A cross-head *A* (fig. 49) fixed to each of the piston-rods is connected to the piston-rods of a pair of oscillating cylinders *B*, *B*, which contain water and communicate with a reservoir full of air compressed to a pressure of about 300 lb per square inch. When the stroke (which takes place in the direction of the arrow) begins the pistons are at first forced in, and work is at first done by the main piston-rod, through the compensating cylinders *B*, *B*, on the compressed air in the reservoir. This continues until the cross-head has advanced so that the cylinders stand at right angles to the line of stroke. Then for the remainder of the stroke the compensating cylinders assist in driving the main piston, and the compressed air gives out the energy which it stored in the earlier portion. The volume of the air reservoir is so much greater than the volume of the cylinders, *B*, *B*, that the air pressure remains nearly constant throughout the stroke. Any leakage from the cylinder or reservoir is made good by a small pump which the engine drives.

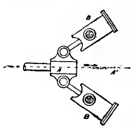

FIG. 49.

99. *Pulsometer.*—Hall's "pulsometer" is a peculiar pumping engine without cylinder or piston, which may be regarded as the modern representative of the engine of Savery. The sectional view, fig. 50, shows its principal parts. There are two chambers A, A′, narrowing towards the top, where the steam-pipe B enters. A ball-valve C allows steam to pass into one of the chambers and closes the other. Steam entering (say) the right-hand chamber forces water out of it past the clack-valve V into a delivery passage D, which is connected with an air-vessel. When the water level in A sinks so far that steam begins to blow through the delivery passage, the water and steam are disturbed and so brought into intimate contact, the steam in A is condensed, and a partial vacuum is formed. This causes the ball-valve C to rock over and close the top of A, while water rises from the suction-pipe E to fill that chamber. At the same time steam begins to enter the other chamber A′, discharging water from it, and the same series of actions is repeated in either chamber alternately. While the water is being driven out there is comparatively little condensation of steam, partly because the shape of the vessel does not promote the formation of eddies, and partly because there is a cushion of air between the steam and the water. Near the top of each chamber is a small air-valve opening inwards, which allows a little air to enter each time a vacuum is formed. When any steam is condensed, the air mixed with it remains on the cold surface and forms a non-conducting layer. The pulsometer is, of course, far from efficient as a thermodynamic engine, but its suitability for situations where other steam-pumps cannot be used, and the extreme simplicity of its working parts, make it valuable in certain cases.

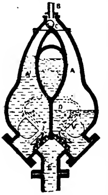

FIG. 50.—Pulsometer.

100. *Rotary Engines.*—From the earliest days of the rotative engine attempts have been made to avoid the intermittent reciprocating motion which an ordinary piston engine first produces and then converts into motion of rotation. Murdoch, the contemporary of Watt, proposed an engine consisting of a pair of spur-wheels gearing with one another in a chamber through which steam passed by being carried round the outer sides of the wheels in the spaces between successive teeth.

In Dudgeon's wheel engine the steam was admitted by ports in side-plates into the clearance space behind teeth in gear with one another, just after they had passed the line of centres. From that point to the end of the arc of contact the clearance space increased in volume; and it was therefore possible, by stopping the admission of steam at an intermediate point, to work expansively. The difficulty of maintaining steam-tight connexion between the teeth and the side-plates on which the faces of the wheels slide is obvious; and the same difficulty has prevented the success of many other forms of rotary engine. These have been devised in immense variety, in many cases, it would seem, with the idea that a distinct mechanical advantage was to be secured by avoiding the reciprocating motion of a piston. In point of fact, however, very few forms entirely escape having pieces with reciprocating motion. In all rotary engines, with the exception of steam turbines—where work is done not by pressure but by the kinetic impulse of steam—there are steam chambers which alternately expand and contract in volume, and this action usually takes place through a more or less veiled reciprocation of working parts. So long as engines work at a moderate speed there is little advantage in avoiding reciprocation; the alternate starting and stopping of piston and piston-rod does not affect materially the frictional efficiency, throws no deleterious strain on the joints, and need not disturb the equilibrium of the machine as a whole. The case is different when very high speeds are concerned; it is then desirable as far as possible to limit the amount of reciprocating motion and to reduce the masses that partake in it.

101. *Types of Marine Engines.*—The early steamers were fitted with paddle-wheels, and the engines used to drive them were for the most part modified beam engines. Bell's "Comet" was driven by a species of inverted beam engine, and another form of inverted beam, known as the *side-lever* engine, was for long a favourite with marine engineers. In the side-lever engine the cylinder was vertical, and the piston-rod projected through the top. From a crosshead on the rod a pair of links, one on each side of the cylinder, led down to the ends of a pair of horizontal beams or levers below, which oscillated about a fixed gudgeon at or near the middle of their length. The two levers were joined at their other ends by a cross-tail, from which a connecting-rod was taken to the crank above. The side-lever engine is now obsolete. In American practice, engines of the beam type, with a braced-beam supported on A frames above the deck, are still common in river-steamers and coasters. An old form of direct-acting paddle-engine was the *steeple* engine, in which the cylinder was set vertically below the crank. Two piston-rods projected through the top of the cylinder, one on each side of the shaft and of the crank. They were united by a crosshead sliding in vertical guides, and from this a return-connecting-rod led to the crank. Modern paddle-wheel engines are usually of one of the following types. (1) In *oscillating cylinder* engines the cylinders are set under the crank-shaft, and the piston-rods are directly connected to the cranks. The cylinders are supported on trunnions which give them the necessary freedom of oscillation to follow the movement of the crank. Steam is admitted through the trunnions to slide-valves on the sides of the cylinders. In some instances the mean position of the cylinders is inclined instead of vertical; and oscillating engines have been arranged with one cylinder before and another behind the shaft, both pistons working on one crank. The oscillating cylinder type is best adapted for what would now be considered comparatively low pressures of steam. (2) *Diagonal* engines are direct-acting engines of the ordinary connecting-rod type, with the cylinders fixed on an inclined bed and the guides sloping up towards the shaft.

When the screw-propeller began to take the place of paddle-wheels in ocean steamers, the increased speed which it required was at first supplied by using spur-wheel gearing in conjunction with one of the forms of engines then usual in paddle steamers.

After a time types of engine better suited to the screw were introduced, and were driven fast enough to be connected directly to the screw-shaft. The smallness of the horizontal space on either side of the shaft formed an obstacle to the use of horizontal engines, but this difficulty was overcome in several ways. In Penn's *trunk* engine, now obsolete, the engine was shortened by attaching the connecting-rod directly to the piston, and using a hollow piston-rod, called a trunk, large enough to allow the connecting-rod to oscillate inside it. The *return-connecting-rod* engine was another horizontal form at one time used in the British navy. It was a steeple engine placed horizontally, with two, and in some cases four, piston-rods in each cylinder. The piston-rods passed clear of the shaft and the crank, and were joined beyond it in a guided crosshead, from which a connecting-rod returned.

102. *Inverted Vertical Engines.*—Both in the navy and in merchant ocean steamers one general type of engine is universal, where the reciprocating engine has not yet been displaced by the steam turbine. This is the inverted vertical direct-acting engine, with two or more cylinders placed side by side directly over the shaft. Two, three and four cranks are employed, the arrangement with four cranks being specially suitable, as has already been pointed out, when the balance of the engine at high speeds has to be secured. As a rule naval engines are triple compound, and those of merchant vessels either triple or quadruple. In vessels of high speed and power the engines are arranged in twin sets, on two shafts with twin screw propellers.

The marine engine is always furnished with a surface condenser, consisting of a multitude of brass tubes about ¾ in. in diameter cooled by sea-water which is caused to circulate through the condenser by means of a circulating pump. This pump and also the air pump are often driven independently of the main engine.

103. It is in marine practice that the largest examples of engines are to be found. The triple expansion engines of the "Campania" and "Lucania," which develop 30,000 h.p., consist of twin sets, on two shafts, each set having three cranks and five cylinders, two of 37 in., one of 79 in. and two of 98 in. diameter, with a stroke of 69 in. In the "Kaiser Wilhelm der Grosse" engines of the same power are arranged in twin sets, each set consisting of four cylinders, one of 52 in. diameter, one of 89 and two of 96·4, the four giving triple expansion and working on four cranks. The "Deutschland" develops 36,000 h.p. with twin sets, each of which comprises two 36·6-in. cylinders, one 73·6-in., one 103·9-in. and two 106·3-in. with a stroke of 72·8 in. In the "Kaiser Wilhelm II." each of the twin shafts is driven by two 3-crank 4-cylinder quadruple expansion engines, the diameters being 37·4, 49·2, 74·8 and 112·2 in. and a stroke of 70·9 in. With a working pressure of 225 ℔ per square inch these engines develop in all 40,000 h.p. These are examples of the most powerful reciprocating engines used in the propulsion of ships, but the successful application of the Parsons turbine to marine use has enabled even these powers to be greatly surpassed.

104. *Locomotive Engines.*—The ordinary locomotive consists of a pair of direct-acting horizontal or nearly horizontal engines, fixed in a rigid frame under the front end of the boiler, and coupled to the same shaft by cranks at right angles, each with a single slide-valve worked by a link-motion, or by a form of radial gear. The engine is non-condensing, except in a very few special cases, and the exhaust steam, delivered at the base of the funnel through a blast-pipe, serves to produce a draught of air through the furnace. In some instances a portion of the exhaust steam, amounting to about one-fifth of the whole, is diverted to heat the feed-water. In tank engines the feed-water is carried in tanks on the engine itself; in other engines it is carried behind in a tender.

On the shaft are a pair of driving-wheels, whose frictional adhesion to the rails furnishes the necessary tractive force. In some engines a single pair of driving-wheels are used; in many more a greater tractive force is secured by having two equal driving-wheels on each side, connected by a coupling-rod between pins on the outside of the wheels. In some engines a still greater proportion of the whole weight is utilized to give tractive force by coupling three or more wheels on each side.

It is now general to have under the front of the engine two or four smaller wheels which do not form part of the driving system. These are carried in a *bogie*, that is, a small truck upon which the front end of the boiler rests by a swivel-pin or plate which allows the bogie to turn, so as to adapt itself to curves in the line, and thus obviate the grinding of tyres and danger of derailment which would be caused by using a long rigid wheel base. The bogie appears to have been of English origin;[1] it was brought into general use in America, and is now common in English as well as in American practice. Instead of a four-wheeled bogie, a single pair of leading wheels are also used, carried by a Bissel *pony* truck, which has a swing-bolster pivoted by a radius bar about a point some distance behind the axis of the wheels. This has the advantage of combining lateral with radial movement of the wheels, both being required if the wheel base is to be properly accommodated to the curve. Another method of getting lateral and radial freedom is the plan used by F. W. Webb of carrying the leading axle in a box curved to the arc of a circle, and free to slide laterally for a short distance, under the control of springs, in curved guides.[2]

In *inside-cylinder* engines the cylinders are placed side by side within the frame of the engine, and their connecting-rods work on cranks in the driving shaft. In *outside-cylinder* engines the cylinders are spread apart far enough to lie outside the frame of the engine, and to work on crank-pins on the outsides of the driving wheels. This dispenses with the cranked axle, which is the weakest part of a locomotive engine. Owing to the frequent alternation of strain to which it is subject, a locomotive crank axle is peculiarly liable to rupture, and has to be removed after a certain amount of use.

The outside-cylinder type is adopted by several British makers; in America it is almost universal. There the cylinders are in castings which are bolted together to form a saddle on which the bottom of the smoke-box sits. The slide-valves are on the tops of the cylinders, and are worked through rocking levers from an ordinary link-motion. Fig. 51, which is a half section through one cylinder of an American locomotive, by the Baldwin Company of Philadelphia, shows the position of the cylinders and valves.

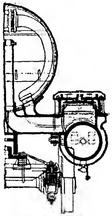

Fig. 51.—American Outside-Cylinder Locomotive.

In inside-cylinder engines the slide-valves are frequently placed back to back in a single valve-chest between the cylinders. The width of the engine within the frame leaves little room for them there, and they are reduced to the flattest possible form, in some cases with split ports, half above and half below a partition in a central horizontal plane. In some engines the valves are below the cylinders: in many others the valves work on horizontal planes above the cylinders; this position is specially suitable when some form of radial gear is used instead of the link-motion. Radial valve-gears have the advantage, which is of considerable moment in inside-cylinder engines, that a part of the shaft's length which would otherwise be needed for eccentrics is available to increase the width of main bearings and crank-pins, and to strengthen the crank-cheeks.

The principle of compounding has often been applied to locomotive engines, but without much advantage. On this subject the reader should refer to the article RAILWAY: § *Locomotive Power*. A more important modern departure is the use of highly superheated steam, which in many locomotives has been attended with conspicuous success.

[1] *Proc. Inst. Civ. Eng.*, liii. 3, p. 50.
[2] *Proc. Inst. Mech. Eng.* (1883).

105. *Steam Turbines.*—Steam turbines are distinguished from all other types of steam engine by the fact that their action involves a double transformation of energy. The heat energy present in the steam is first employed to set the steam itself in motion, giving it kinetic energy, and this in turn is employed to do work on the turbine blades. A brief account of the main principles involved will make the action of the various types of steam turbine more intelligible.

106. *Theory of the Steam-jet.*—Consider an element of steam, of unit mass, acquiring kinetic energy in the expansion of the steam through a nozzle or other channel, from a region of pressure p_1 to a region of lower pressure p_2. Its volume changes from v_1 to v_2 in the process. The work done upon it by steam from behind is p_1v_1. The work which it does on the steam in front is p_2v_2. The net amount of work done upon it is therefore $p_1v_1-p_2v_2$. Its velocity changes from V_1 to V_2; the kinetic energy which it gains is therefore $(V_2^2-V_1^2)/2g$. The internal energy changes from E_1 to E_2. Hence by the conservation of energy

$$(V_2^2-V_1^2)/2g=J(E_1-E_2)+p_1v_1-p_2v_2$$

which may be written

$$(V_2^2-V_1^2)/2g=J(I_1-I_2),$$

where I is the total heat (§ 31), which is equal to $E+pv/J$. It is assumed here that the action is adiabatic in the sense that no heat is received by the steam or given up by it to other bodies as the process goes on.

It is usual to speak of the change of I as the "heat drop" which the steam undergoes in acquiring velocity. When the heat drop is known the gain in velocity is readily found, as above. In determining the best drop account must, of course, be taken of the wetness of the steam, or of its superheat if it has any. Thus, for superheated steam $I=I_s+\kappa(t'-t)$ where I_s is the total heat of saturated steam at the same pressure and $\kappa(t'-t)$ represents the heat taken up in the process of superheating to the actual temperature t' from the temperature of saturation t. And for wet steam $I=I_w+qL$ where I_w is the total heat of water, L the latent heat, and q is the dryness fraction.

During this process of expansion, which we assume to be adiabatic, the steam becomes wet, and the value of q accordingly falls. As has been shown in § 36, the dryness may be found at any stage in adiabatic expansion from the formula—

$$q=\frac{\tau}{L}\left(\frac{q_1L_1}{\tau_1}+\log_\epsilon\frac{\tau_1}{\tau}\right),$$

or it may be determined by measurement from the entropy-temperature diagram. A still more convenient diagram in which the heat drop can be directly measured is one introduced by Mollier, in which the co-ordinates are the entropy and the total heat (see Mollier, *loc. cit.*, or Ewing's *Steam Engine*).

The pressure-volume diagram gives a very useful alternative means of finding the heat drop or energy available for transformation. Consider steam or any other gas supplied at pressure p_1 and expanding to pressure p_2, at which pressure it is discharged. The work which it does is measured by the area ABCD of the pressure-volume diagram (fig. 52), namely,

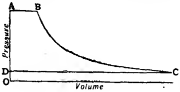

FIG. 52.

$$\int_{p_2}^{p_1}vdp.$$

If this work is wholly done upon this steam in giving it velocity, the kinetic energy acquired is equal to it, that is

$$(V_2^2-V_1^2)/2g=\int_{p_2}^{p_1}vdp.$$

We have already seen (§ 41) that in adiabatic expansion this integral measures the heat drop, being equal to I_1-I_2.

If the mode of expansion is such as to make pv^n=constant, n being any index, then

$$\int_{p_2}^{p_1}vdp=\frac{n}{n-1}(p_1v_1-p_2v_2)$$
$$=\frac{n}{n-1}\left(1-D^{\frac{n-1}{n}}\right)p_1v_1,$$

where D is the ratio in which the pressure falls, namely p_2/p_1.

Now the adiabatic expansion of steam, starting from an initially dry saturated state, is very approximately represented by the formula $pv^{1\cdot135}$=constant. Hence the area of the pressure-volume diagram, which under these conditions measures the work theoretically obtainable, is equal to $8\cdot41(1-D^{0\cdot119})p_1v_1$, a quantity which will be found on evaluation to agree closely with the value of I_1-I_2.

107. *Form of the Jet in Adiabatic Expansion.*—As expansion proceeds the volume of the steam, per pound, at any stage is found by multiplying the volume of 1 ℔ of saturated steam, at the pressure then reached, by the dryness fraction q. On comparing the velocity acquired at any intermediate stage of expansion—as calculated from the heat drop down to that stage—with the increase in volume, it will be found that in the earliest stages the gain in velocity is relatively great, but as expansion proceeds the increase in volume outstrips the increase in velocity. Hence the proper form for a nozzle to give adiabatic expansion is one in which the area of section at first contracts and afterwards becomes enlarged. The area of section to be provided for the discharge is found by dividing the volume v at each stage of the velocity V acquired up to that stage, and the ratio v/V at first diminishes and afterwards increases as the expansion proceeds. Take, for instance, as a numerical example, a case in which dry saturated steam is admitted to a nozzle at an absolute pressure of 213 ℔ per sq. in., and expands adiabatically, giving itself velocity, until the pressure falls to 1·7 per sq. in. It will be found on working out numerical values that until the pressure falls to about 123 ℔ per sq. in. the steam is gaining velocity so rapidly that though its volume is expanding the stream-lines are convergent. Below that pressure, however, the augmentation of volume is relatively so great that a larger and larger area of section has to be provided for the flow. Thus, when the pressure is 123 ℔ per sq. in. the dryness q is 0·96, the volume per pound is 3·51 cub. ft., the heat drop is 25¼ thermal units, giving a velocity of 1510 ft. per second. Consequently, the area of the stream is 0·00233 sq. ft. per pound of flow, and this is the minimum value. When the pressure falls to 1·7 ℔ per sq. in. the dryness q is 0·784, the volume per pound is 157·8 cub. ft., the heat drop is 175·7 thermal units, giving a velocity of 3980 ft. per second, and consequently the area of the stream is 0·0396 sq. ft. per pound of flow.

108. *De Laval's Divergent Nozzle.*—It is on this basis that De Laval's divergent nozzle is designed. The "throat" or smallest section is approached by a more or less rounded entrance, allowing the stream-lines to converge, and from the throat outwards the nozzle expands in any gradual manner, generally in fact as a simple cone (fig. 53). In the example just given the final area of section would be seventeen times that of the throat to provide for adiabatic expansion down to a pressure of 1·7 ℔ per sq. in. With any final area less than this the pressure at exit would be higher than 1·7 ℔; it would in fact adjust itself to give a value of v/V corresponding to the area, and the remainder of the pressure drop would be wasted. For expansion to atmospheric pressure (14·7 per sq. in.) the area at exit would be 3·14 times that of the throat.

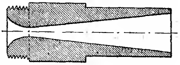

FIG. 53.

The equation of velocity

$$\frac{V^2}{2g}=\frac{n}{n-1}\left(1-D^{\frac{n-1}{n}}\right)p_1v_1$$

may be applied to calculate generally the discharge per square foot of stream section, and hence to find at what point in the fall of pressure this discharge becomes a maximum—in other words, to determine the pressure at the throat. Since $pv^n=p_1v_1^n$

$$v=v_1/D^{\frac{1}{n}}\quad\text{where } D=p/p_1.$$

The discharge per square foot when the volume is v is

$$Q=\frac{V}{v}=\frac{VD^{\frac{1}{n}}}{v_1}=\sqrt{\left\{\frac{2gn}{n-1}\cdot\frac{p_1}{v_1}\left(D^{\frac{2}{n}}-D^{\frac{n+1}{n}}\right)\right\}}.$$

Q will be a maximum when dQ/dD is zero, which occurs when

$$D=\left(\frac{2}{n+1}\right)^{\frac{n}{n-1}}.$$

This result is general for any gas. With saturated steam, n being 1·135, Q is a maximum when D=0·577, that is to say, the pressure at the throat is 57·7% of the initial pressure, a result which agrees with the figures quoted above for a particular case.

The maximum value of Q, namely the discharge in pounds per square foot at the throat, is

$$3\cdot6\sqrt{(p_1/v_1)},$$

and the velocity there is $5\cdot85\sqrt{(p_1v_1)}$. In these expressions p_1 is the initial pressure in pounds per square foot.

109. From these considerations it follows that, provided the final pressure is less than 0·577 times the initial pressure, the total discharge depends simply on the least area of section of the nozzle and on the initial pressure, and is independent of the final pressure. By continuing the expansion in a divergent nozzle, after the throat is passed, the amount of discharge is not increased, but the steam is caused to acquire a greater velocity of exit, namely the velocity corresponding to the augmented pressure range.

110. When the pressure drop is small (p_2 greater than 0·577 p_1) the full velocity due to the drop is obtained without the use of a

divergent nozzle. This is the case, for instance, in the Parsons turbine, where the whole expansion is divided into many stages each of which involves only a small drop in pressure.

111. *Influence of Friction.*—We have dealt so far with the ideal case of no friction, and have taken the whole work of expansion as going to produce kinetic energy in the jet. But under real conditions there is a progressive dissipation of energy through friction; as expansion proceeds the steam loses part of its kinetic energy which is restored to it as heat. Thus, at every stage in the process the velocity acquired is less than it would be in frictionless adiabatic expansion, but the steam is drier and its volume is greater in consequence of the restored heat. Referring to the entropy-temperature diagram (fig. 54) the process of expansion under conditions involving friction is represented not by the adiabatic line *cd* but by some such line as *cg* lying between the adiabatic line and the saturation line *cf*. The final condition of dryness is *ag*/*af* instead of *ad*/*af*. During this expansion the effect of friction, as regards the entropy, is equivalent to the communication to the substance of a quantity of heat represented by the area *pcgr*. Hence that area represents the work converted by friction into heat. The whole work done during expansion is the area *abcg*, which is more than before by the area *dcg*. The difference, namely *abcg minus pcgr*, represents what may be called the *net* heat drop when friction is allowed for: it represents what is effectively available for giving kinetic energy to the jet. This net area may also be expressed as equal to *abcd minus pdgr*. Compared with frictionless adiabatic expansion the net loss resulting from friction is the area *pdgr*. The volume is increased in the ratio of *ag* to *ad*, and this has to be taken account of in determining the proper dimensions of the divergent nozzle.

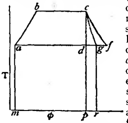

Fig. 54.

112. Turning now to the question of utilizing the kinetic energy of steam in a steam turbine, it will be clear from the figures that have been given that if the whole heat drop is allowed to give kinetic energy to the steam in one operation, as in the De Laval nozzle, a velocity of about 4000 ft. per second has to be dealt with. To take advantage of a jet in the most efficient manner in a turbine consisting of a single wheel the velocity of the buckets against which the steam impinges should be nearly one half the velocity of the stream. But a peripheral velocity approaching 2000 ft. per second is impracticable. Apart from the difficulties which it would involve as regards gearing down to such a speed as would serve for the driving of other machines, which are to employ the power, there are no materials of construction fitted to withstand the forces caused by rotation at such a speed.

Hence it is advantageous to divide the process into stages. This may be done by using more than one wheel to absorb the kinetic energy of the jet, as is done in the Curtis turbine, or by dividing the heat drop into many steps, making each of these so small that the steam never acquires an inconveniently great velocity, as is done in the Parsons turbine. Turbines which employ one or other of these two methods, or a combination of both, achieve a greater economy of steam than is practicable with a single wheel.

113. *De Laval Turbine.*—Thanks, however, to the inventions of De Laval, the single expansion single wheel type of turbine, with buckets in the rim, has been brought to a degree of efficiency which, while considerably less than is reached in compound turbines, is still remarkably good. This has been done by the use of the divergent nozzle and with the help of mechanical devices which enable the peripheral speed to be very high, though even with the help of these devices the speed of the buckets falls considerably short of that which would be suitable to the velocity of the jet. In De Laval's turbine the steam expands at one step from the full pressure of the supply to the pressure of the exhaust by discharge in the form of a jet from a divergent nozzle. It then acts on a ring of buckets or blades in much the same way as the jet of water acts on the buckets of a Pelton wheel or other form of pure impulse turbine. To utilize a fair fraction of the kinetic energy of the jet the blades have to run at an enormous velocity, and the speed of the shaft which carries them is so great that gearing down is resorted to before the motion is applied to useful purposes. The general arrangement of the steam nozzle and turbine blades is illustrated in fig. 55. The blades project from the circumference of a disk-shaped wheel and form a complete ring round it, only a few of the blades being shown in the sketch. The increasing section of the nozzle is calculated with reference to the final pressure, according to the principles already explained. The jet impinges at one side of the wheel and escapes at the other after having had its direction of motion nearly reversed. The expansion in the nozzle is carried to atmospheric pressure, or near it, if the turbine is to be used without a condenser; but in many cases an ejector condenser is employed, and when that is done the nozzle is of a form which adapts it to expand the steam to a correspondingly lower pressure. It is only in the smaller sizes of these turbines that a single nozzle is used; in the larger steam turbines, as in large Pelton wheels, several nozzles are applied at intervals along the circumference of the disk. The peripheral velocity of the blades ranges from about 500 ft. per second in the smallest sizes (5 h.p.) up to nearly 1400 ft. per second in turbines of 300 h.p. In a 50 h.p. De Laval turbine the shaft which carries the turbine disk makes 16,000 revolutions per minute; in the 5 h.p. size it makes as many as 30,000 revolutions per minute. A turbine developing 300 h.p. uses a wheel 30 in. in diameter, running at over 10,000 revolutions per minute, with a peripheral speed of nearly 1400 ft. per second. These enormous speeds are made possible by the ingenious device of using a flexible shaft, which protects the bearings and foundations from the vibration which any want of balance would otherwise produce. The elasticity of the shaft is such that its period of transverse vibration is much longer than the time taken to complete a revolution. The high-speed shaft which carries the turbine disk is geared, by means of double helical wheels with teeth of specially fine pitch, to a second-motion shaft, which runs at one-tenth of the speed of the first; and from this the motion is taken, by direct coupling or otherwise, to the machine which the turbine is to drive. The wheel carrying the buckets is much thickened towards the axis to adapt it to withstand the high stresses arising from its rotation. Turbines of this class in sizes up to 300 or 400 h.p. are now in extensive use for driving dynamos, fans and centrifugal pumps. Compared with the Parsons turbine, De Laval's lends itself well to work where small amounts of power are wanted, and there it achieves a higher efficiency, but in large sizes the Parsons turbine is much the more efficient of the two. Trials of a De Laval turbine used with a condenser, and developing about 63 h.p., have shown an average steam consumption at the rate of about 20 lb per brake-horse-power-hour, and even better results are reported in turbines of a larger size.

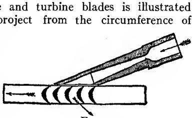

Fig. 55.

114. *Action of the Jet in De Laval's Turbine.*—In entering the turbine the jet is inclined at an angle α to the plane of the wheel. Calling its initial velocity V_1 and the velocity of the buckets u we have, as in fig. 56, V_2 for the velocity of the steam relatively to the wheel on admission. A line AB parallel to V_2 therefore determines the proper angle of the blade or bucket on the entrance side if the steam is to enter without shock. As the steam passes through the blade channel the magnitude of this relative velocity does not change, except that it is a little reduced on account of friction. The action is one of pure impulse; there is no change of pressure during the passage, and consequently no acceleration of the steam through drop in pressure after once it has left the nozzle. Hence V_3, the relative velocity at exit may (neglecting friction) be taken as equal to V_2. The direction of V_3 or BC is tangent to the exit side of the bucket.

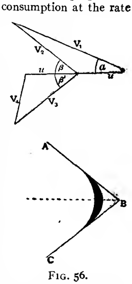

Fig. 56.

Compounding V_3 with u we find V_4, which is the absolute velocity of the steam after exit, and this should be no greater than is required to get the steam clear of the wheel. The most favourable condition of running would be when the bucket velocity u is such that V_4 is perpendicular to the plane of the wheel, for V_4 would then have its least possible value. Assuming the angle of discharge β' to be equal to β, we should in that event have $u = \frac{1}{2}V_1\cos\alpha$, which approximates more and more closely to $\frac{1}{2}V_1$ the smaller α is made. The ideal efficiency would be $(V_1^2 - V_4^2)/V_1^2$ or $1 - \sin^2\alpha$ in a turbine in which the jet enters the buckets without shock and travels over them without friction. In practice α is about 20°. Owing to the impossibility of making the bucket speed so high as the above condition implies the steam enters the buckets of a De Laval turbine with some shock and leaves them with a velocity inclined to the plane of the wheel, with a backward component, and the turbine loses something in efficiency through this exit velocity being greater than the ideal minimum.

Taking a test of a De Laval turbine of 300 h.p. in which the steam consumed was 15·6 ℔ per horse-power-hour, Stodola estimates that the losses in the nozzle amount to about 15% of the available energy or total heat drop, the losses in the buckets (due to friction and to eddy currents set up by shock) to 21% and the losses due to the velocity retained by the steam at exit to nearly 5%. The losses due to friction in the mechanism consume about 5% more, leaving a net return of about 54% of the available energy.

115. *Curtis Turbine.*—The Curtis turbine, like that of De Laval, is a pure impulse turbine, but the velocity of the jet is extracted not by one ring of buckets but by a series of rings, each of which extracts a certain part. Between the first and second rings of buckets there are fixed guide blades which serve to turn the remaining motion of the steam into a direction proper for its action on the second ring, and so on. The jet, having acquired its velocity in a nozzle in the first place, often acts on three successive rings of moving buckets, with two sets of fixed guide blades between, the three co-operating to extract its kinetic energy. But the Curtis turbine is generally compound in the further sense that the total drop from admission to condenser pressure is itself divided into two, three or more stages, the steam acquiring velocity anew at each stage and then giving up that velocity in passing through a series of impulse turbine rings generally either two or three in number before undergoing the next drop in pressure.

116. *Action of the Steam in the Curtis Turbine.*—In this division of the heat drop or pressure drop into stages Curtis follows Parsons. The distinctive feature in Curtis is the multi-impulse action which occurs at each pressure stage. This is illustrated in the diagram (fig. 57), which shows the nozzle and

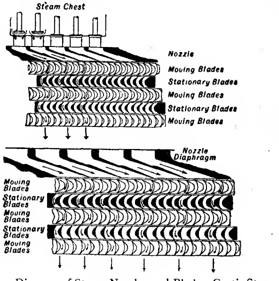

FIG. 57.—Diagram of Steam Nozzles and Blades, Curtis Steam Turbine.

blades of a two-stage Curtis turbine, with three rings of moving blades or buckets in each stage, arranged, of course, round the periphery of a wheel. The velocity acquired in the nozzles is extracted as the steam pursues its sinuous course between moving and fixed blades, and it leaves the third ring in each case with only a small residual velocity, the direction of which is approximately parallel to the axis of the wheel. The changes of velocity are illustrated in fig. 58, which, for the sake of simplification, is drawn for the ideal case of no friction. There u is the velocity of the buckets, V_1 the initial velocity of the jet, and V_2 the initial relative velocity on entrance to the first moving ring. V_3 is the absolute velocity on entering the second moving ring, and V_4 the relative velocity. V_5 is the absolute velocity on entering the third moving ring and V_6 the relative velocity. Finally, V_7 is the absolute velocity on leaving the third moving

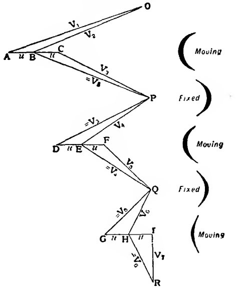

FIG. 58.

ring, and this in the example here drawn is parallel to the axis of the turbine. The first moving blades have sides parallel to OB, BP; the first fixed blades have sides parallel to CP, PD. The second moving blades have sides parallel to PE, EQ; the second fixed blades to FQ, QG, and the third moving blades to QH, HR.

The steam then passes on to a second set of divergent nozzles in which it undergoes a second drop in pressure, acquiring velocity afresh, which it loses as before in passing through a set of three rings of moving buckets. In some Curtis turbines this is followed by a third and often a fourth similar process before the condenser is reached. In a four-stage Curtis turbine the speed of the buckets is usually about 400 ft. per second; the steam issues from each set of nozzles with a velocity of about 2000 ft. per second, and each set of moving rings reduces this by something like 400 ft. per second. The losses due to steam friction are somewhat serious, although the blade speed in each set is sufficient to let the steam enter without shock; on the other hand, the Curtis turbine escapes to a great extent losses due to leakage which are present in the Parsons type. The velocity diagram shown in fig. 58 may readily be modified to allow for effects of friction. Owing to the progressive reduction of velocity in passing from ring to ring a larger and larger area of blade opening is required, and this is provided for by making the height of the blades increase in the successive rings of each series.

117. *Performance of Curtis Turbines.*—Curtis turbines have been successfully applied in large sizes, especially in America, to drive electric generators, with outputs of as much as 9000 kilowatts, and in a few instances they have been adapted to marine propulsion. In large sizes, and using moderately superheated steam, the Curtis turbine has achieved a high degree of efficiency. The advantage of superheating, in any type of turbine, is to reduce the wetness which the steam develops as it expands during work. The prejudicial effect of wetness is chiefly that it increases friction, especially in the later stages of the expansion. Tests of Curtis turbines show that they maintain a very uniform efficiency throughout a wide range of loads, and are capable of being much overloaded without

material increase in the ratio of steam consumption to output. In tests of a 9000 kilowatt Curtis turbine using steam of about 200 lb pressure and 80° C. superheat, with a vacuum of $29\frac{1}{2}$ in. the consumption of steam is reported to have been only 13 lb per kilowatt-hour, and this figure remained almost constant for loads ranging from 8000 to 12,000 kilowatts. In a 5000 kilowatt turbine under very similar conditions the consumption is reported to have been $13\frac{1}{2}$ lb per kilowatt-hour. In the usual arrangement of the Curtis turbine the shaft is vertical and the wheels lie in horizontal planes, the weight of the revolving parts being taken by a footstep bearing with forced lubrication, and the electric generator is mounted on the top. There are usually in the large sizes four stages of expansion, each stage being separated from the one above it by a diaphragm plate containing the nozzles in which the next step in velocity is acquired. The expansion has been divided into as many as seven stages in a Curtis turbine for marine use, the shaft being then horizontal, and in all except the first stage in that example the pressure drop is so comparatively small as not to require divergent nozzles.

118. *Parsons Turbines.*—In the turbines of De Laval and Curtis the action on the moving blades or buckets is entirely one of impulse. No drop of pressure occurs while the steam is passing the moving blades, and its velocity relative to the blade surface undergoes no change except such as is brought about by friction. In the Parsons turbine, on the other hand, there is a *reaction* effect. The steam acquires relative velocity and loses pressure as it passes each ring of moving blades: in this respect the action in the moving blades is like the action in the fixed blades. Each pair of fixed and moving rings makes up what is called a "stage" and may be said to constitute a separate turbine: the whole is a series of many such stages. In each stage the drop in pressure and in heat is divided equally between the fixed and moving element, the exit and entrance angles and the form of the blades generally being alike in both. The number of stages depends on what peripheral speed it is convenient to use. Where comparatively high blade speeds are practicable, as in turbines for driving electric generators, the steam is allowed to acquire a fairly high velocity at each ring of blades, and in such cases so few as 45 stages may be suitable. In large marine turbines, on the other hand, where the number of revolutions per minute has to be kept low in the interests of propeller efficiency, the blade speeds cannot be kept high without making the diameters unduly great, and consequently more stages are required: in such turbines the number of stages may be from 100 to 200. The general relation of fixed to moving blades and the characteristic form of both will be seen from fig. 59.

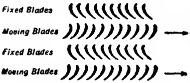

FIG. 59.—Fixed and Moving Blades of Parsons Turbine.

Fig. 60 shows a complete Parsons turbine of 1000 kilowatts capacity in longitudinal section through the casing. The fixed blades are caulked with separating distance-pieces into grooves turned on the inner surface of the case and project inwards: the moving blades are similarly secured in grooves which are turned on the surface of the rotating drum. Between drum and case there is an annular space fitted in this way with successive rings of fixed and moving blades. There is considerable longitudinal clearance from ring to ring, but over the tips of the blades the clearance is reduced to the smallest possible amount consistent with safety against contact (generally from 15 to 30 thousandths of an inch in turbines of moderate size). Steam enters at A, expands through all the rings of blades in turn and escapes to the condenser at B. To provide for the increase in its volume the size of the blade passages enlarges progressively from the high to the low pressure end. In the example shown this is done partly by lengthening the blades and partly by increasing the circumference of the drum, which has the further effect of increasing the blade velocity, so that the expanded steam not only has a larger area of passage open to it but is also allowed to move faster, and consequently each unit of the area is more effective in giving it vent. Instead of attempting to make the change in passage area continuous from ring to ring, as the ideal turbine would require, it is done in a limited number of steps and the several rings in each step are kept of the same size. Thus in the example shown in the figure the first step consists of seven pairs of rings or stages, the next two also of seven each, the next three of four each, the next of two and so on. This is convenient for constructive reasons and gives a sufficiently good approximation to the ideal conditions as regards the relation of steam volume to blade-passage-area and velocity.

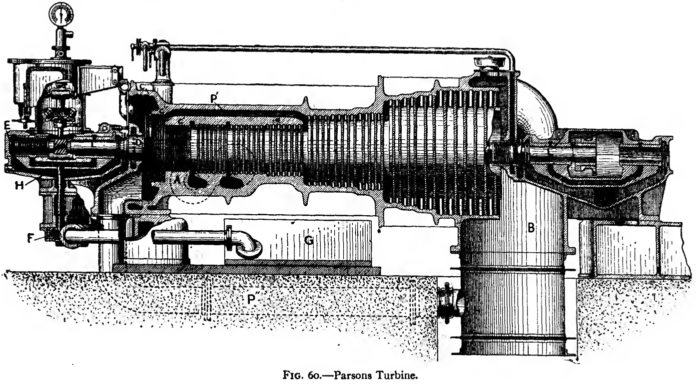

FIG. 60.—Parsons Turbine.

119. *Balance of Longitudinal Forces: Dummies.*—Since the pressure of the steam falls progressively from left to right there is a resultant longitudinal thrust on the drum forcing it to the right, which is balanced by means of "dummy" rings C′ C″ C‴. These correspond in diameter with the several portions of the bladed drum and are connected with them by steam passages which secure that each dummy shall have the same pressure forcing it to the left as tends on the corresponding part of the drum to force it to the right. No steam-tight fit is practicable at the dummies, but leakage of the steam past them is minimized by the device of furnishing the circumference of each dummy with a series of rings which revolve between a corresponding series of fixed rings projecting inwards from the case. The dummy rings do not touch but the clearance spaces are made as fine as possible and the whole forms a labyrinth which offers great resistance to the escape of steam. Substantially the same device is employed to guard against leakage in the glands DD where the shaft leaves the turbine case. There is a "thrust block" E at one end of the shaft which maintains the exact longitudinal position of the revolving part and allows the fine clearances between fixed and moving dummy rings to be adjusted.

120. *Lubrication.*—The main bearings LL are supplied with oil under pressure kept in circulation by a rotary pump F which draws the oil from the tank G. The pump shaft H, which also carries a spring governor to control the speed of the turbine, is driven by a worm on the main shaft. The same oil is circulated over and over again and very little of it is consumed. No oil mixes with the steam, and in this point the turbine has a marked advantage over piston and cylinder engines, which is especially important in marine use. In small fast-running turbines each bearing consists of a bush on which three concentric sleeves are slipped, fitting loosely over one another with a film of oil between. The whole acts as a cushion which damps out any vibration due to want of balance or alignment. In large turbines this device is dispensed with and a solid brass bearing lined with white metal is employed.

121. *Blades.*—The blades are generally of drawn brass, but copper is used for the first few rows in turbines intended for use with superheated steam. In the most usual method of construction they are put one by one into the grooves, along with distance pieces which hold them at the proper angle and proper distance apart, and the distance pieces are caulked to fix them. The length of the blades ranges from a fraction of an inch upwards. In the longest blades of the largest marine steam turbines it is as much as 22 in. When over an inch or so long they are strengthened by a ring of stout wire let into a notch near the tip and extending round the whole circumference. Each blade is "laced" to this by a fine copper binding wire, and the lacing is brazed. For long blades two and even three such rings of supporting wire are introduced at various distances between root and tip. The tips are fined down nearly to a knife-edge so that in the event of contact taking place at the tips between the "rotor" or revolving part, and the "stator" or case, they may grind without being stripped off. The possible causes of such contact are wear of bearings and unequal expansion in heating up. With a proper circulation of oil the former should not take place, and the clearances are made large enough to provide for the latter. Various plans have been devised to facilitate the placing and fixing of the blades. In one method they are slung on a wire which passes through holes in the roots and in the distance pieces and are assembled beforehand in a curved chuck so as to form a sector of the required ring, and are brazed together along with the supporting wires before the segment is put in place. In another method the roots are fixed in a brass rod in which cuts have been machined to receive them; in another the rod in which the roots are secured has holes of the right shape formed in it to receive the blades by being cast round a series of steel cores of the same shape as the blades: the cores are then removed and the blades fixed in the holes.

122. *Drums.*—In small turbines the drums carrying the revolving blades are solid forgings; in large turbines they are also of forged steel but in the form of hollow cylinders turned true inside as well as out. These are supported on the shafts by means of wheel-shaped steel castings near the ends, over which they are shrunk and to which they are fastened by screws the heads of which are riveted over. The case is of cast iron with a longitudinal joint which allows the upper half to be lifted off.

123. *Governing.*—The governor regulates the turbine by causing the steam to be admitted in a series of blasts, the duration of which is automatically adjusted to suit the demand for power. When working at full power the admission is practically continuous; at lower powers the steam valve is opened and closed at rapidly recurring intervals. Each revolution of the governor shaft causes a cam, attached to the governor, to open and close a relay valve which admits steam to a cylinder controlling the position of the main steam valve, which accordingly opens and closes in unison with the relay. The position of the governor determines how long the relay will admit steam to the controlling cylinder, and consequently how long the main valve will be held open in each period. In turbines driving electric generators the control of the relay-valve is sometimes made to depend on variations of the electric pressure produced instead of variations in the speed. In either case the arrangement secures control in a manner remarkably free from frictional interference, and therefore secures a high degree of uniformity in speed or in electric pressure, as the case may be.

To admit of overloading, that is, of working at powers considerably in excess of the full power for which the turbine is designed, provision is often made to allow steam to enter at the full admission pressure beyond the first set of rows of blades: this increases the quantity admitted, and, though the action is somewhat less efficient, more power is developed. An orifice will be seen in fig. 60 a little to the right of the main steam admission orifice, the purpose of which is to allow steam to enter direct to the second set of blades, missing the first seven stages, so that the turbine may cope with overloads.

124. *Absence of Wear.*—Owing to its low steam velocities the Parsons turbine enjoys complete immunity from wear of the blades by the action of the steam. A jet of steam, especially when wet, impinging at very high velocity against a metal surface, has considerable cutting effect, but this is absent at velocities such as are found in these turbines, and it is found that even after prolonged use the blades show no signs of wear and the efficiency of the turbine is unimpaired.

125. *Blade Velocity.*—Experience has shown that the most economical results are obtained when the velocity of the steam through the blades is about twice the velocity of the blades themselves, and the Parsons turbine is accordingly designed with, as far as possible, a constant velocity ratio of about this value. As already explained, it is convenient in practice to divide the expansion into a comparatively small number of steps (about twelve steps is a usual number), giving a constant area of steam passage to the first few rows, a larger area to the next few, and so on. An effect of this is that the velocity ratio varies slightly above and below the value of two to one, but if the steps are not too great this variation is not sufficient materially to affect the efficiency.

If the spindle or drum carrying the moving blades were of the same diameter throughout, the blades at the exhaust end would have to be exceedingly long in order to give passage to the rarefied steam. By increasing the diameter towards the exhaust end the peripheral velocity is increased, and hence the proper velocity for the steam is also increased. The amount of heat drop per ring is consequently greater towards the low-pressure end: in other words, the number of rings for a given drop is reduced. Taking the turbine as a whole, the number of rings will depend on the blade velocity at each step, the relation being such that $\Sigma n V_b^2 =$ constant for a given total drop from admission to exhaust, n being the number of rings whose blade velocity is V_b. It appears that a usual value of this constant is about 1,500,000[1] for the whole range from an admission pressure which may be nearly 200 lb per sq. in. down to condenser pressure.

[1] Speakman, "The Determination of the Principal Dimensions of the Steam Turbine with special reference to Marine Work," *Proc. Inst. Engineers & Shipbuilders in Scotland* (October 1905). On this subject see also Reed, "The Design of Marine Steam Turbines," *Proc. Inst. Civ. Eng.* (February 1909).

The increased diameter at the low-pressure end not only allows the steam velocity to be increased but by enlarging the annulus enables a sufficient area of passage to be provided without unduly lengthening the blades. In the very last stages of the expansion, however, the volume becomes so great that it is not practicable to provide sufficient area by lengthening the blades, and the blades there are accordingly shaped so as to face in a more nearly axial direction and are spaced more widely apart.

The area of the steam passage depends on the angle of the blade. If the blades were indefinitely thin it would be equal to the area of the annulus multiplied by the sine of the angle of discharge, and in practice this is subject to a deduction for the thickness of the blade on the discharge side, as well as to a correction for leakage over the tips. Generally the angle of discharge is about $22\frac{1}{2}°$; and the effective area for the passage of steam is about one-third of the area of the annulus.

Fig. 61 A shows a representative pair of fixed and moving blades of a Parsons turbine, and fig. 61 B the corresponding

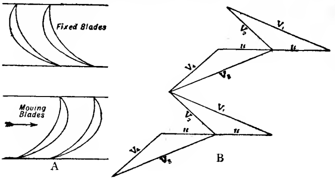

Fig. 61.

velocity diagram for the steam, neglecting effects of friction. V_1 is the exit velocity from the fixed blades, the delivery edges of which are tangent to the direction of V_1. The blade velocity is u which is $\frac{1}{2}V_1$. V_2 is consequently the relative velocity with which the steam enters the moving blades. Approximately, the back surface of these blades is parallel to V_2, but the blades are so thick near the entrance side that their front faces have a considerably different slope and there is therefore some shock at entrance. In passing through the moving blades the relative velocity of the steam over the blades changes from V_2 to V_3. Allowing for the velocity u of the blades themselves, this corresponds to an absolute velocity V_4, with which the steam enters the next set of fixed blades. In these blades it is again accelerated to V_1 and so on.

126. *Calculation of Velocity at each Stage.*—The acceleration of the steam in each row of blades results from a definite heat drop. Or, if we look at the matter from the point of view of the pressure-volume diagram, the acceleration results from the work done on the steam by itself during a drop δp in its pressure. The amount of this work per pound is $v\delta p$ where v is the actual volume per pound. It is convenient in practice to write this in the form $(pv)\delta p/p$, for the product pv changes only slowly as expansion proceeds. In designing a turbine a table of the values of pv throughout the range of pressures from admission to exhaust is prepared, and from these numbers it is easy to calculate the work done at each stage in the expansion, the pressure p and drop in pressure δp being known. In the ideal case with no losses we should have

$$(V_1^2-V_4^2)/2g=(pv)\delta p/p$$

or

$$V_1^2=2g(pv)\delta p/p+V_4^2$$

where V_4 is the velocity before the acceleration due to the drop δp and V_1 is the velocity after.

But under actual conditions the gain of velocity is less than this, owing to blade friction, shock and other sources of loss. The actual velocity depends on the efficiency and on the shape and angles of the blades. It appears that under the conditions which hold in practice in Parsons turbines it is very nearly such that

$$V_1^2=2g(pv)\delta p/p.$$

In this formula, which serves as a means of estimating approximately the velocity for purposes of design, it is to be understood that in calculating the product pv the volume to be taken is that which is actually reached during expansion. The actual volume is affected both by friction and by leakage and is intermediate in value between the volume in adiabatic expansion and the volume corresponding to saturation. In the case of a turbine of 70 % efficiency the actual wetness of the steam is, according to Mr Parsons's experience, about 55 % of that due to adiabatic expansion in the early stages and 60 % in the latest stages. In preparing the table of values of pv figures are accordingly to be taken intermediate between those for saturated steam and for steam expanded adiabatically, and from these is found as above the velocity for any given drop in pressure, and also the volume per pound, for which at each stage in the expansion provision has to be made in designing the effective areas of passage.

The blade speeds used in Parsons turbines rarely exceed 350 ft. per second and are generally a good deal less. In marine forms, where the number of revolutions per minute is limited by considerations of efficiency in the action of the screw propeller, the blade speeds generally range from about 120 to 150 ft. per second, though speeds as low as 80 ft. per second have been used.

127. *Parsons Marine Turbines.*—Marine turbines are divided into distinct high and low pressure parts through which the steam passes in series, each in a separate casing and each driving a separate propeller shaft. The most usual arrangement is to have three propeller shafts; the middle is driven by the high pressure portion of the turbine, and the steam which has done duty in this is then equally divided between two precisely similar low pressure turbines, each on one of two wing shafts. The rotor drum of each turbine has a uniform diameter throughout its length, but the casing is stepped to allow the lengths of the blades to increase as the pressure falls.

The casing which contains each of the two low pressure turbines contains also a turbine for running astern, so that either or both of the two wing shafts may be reversed. Steam is admitted to the reversing turbine direct from the boiler, the centre shaft being then idle. Each astern-driven turbine consists of a comparatively short series of rings of blades, set for running in the reversed direction, developing enough power for this purpose but making no pretensions to high efficiency. The astern turbine, being connected to the condenser, runs *in vacuo* when the ahead turbine is in use and consequently wastes little or no power.

Figs. 62 and 63 are sections of the high pressure and low pressure portions of a typical Parsons marine steam turbine, as designed for the three-shaft arrangement in which the low pressure portion is duplicated. In each figure A is the fixed casing and B is the revolving drum. Steam enters the high pressure turbine (fig. 62) through J and passes out through H. There are 4 "expansions" or steps, with 9 stages or double rows of blades in the first, 9 in the

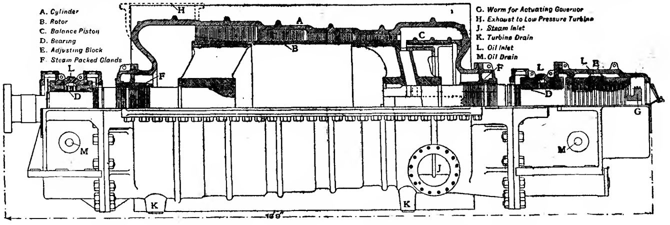

Fig. 62.—Parsons Marine Turbine: High Pressure Part.
Upper half: sectional elevation. Lower half: external view.

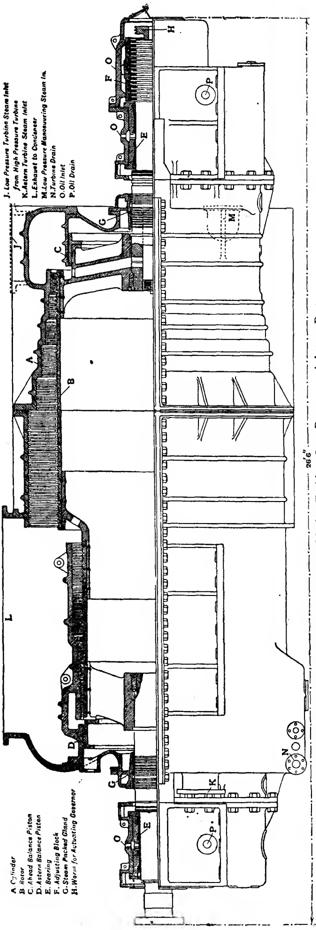

Fig. 63.—Parsons Marine Turbine: Low Pressure and Astern Part.

Upper half: sectional elevation. Lower half: external view.

second, 8 in the third and 8 in the fourth, or 34 stages in all. The low pressure turbine (fig. 63) comprises 28 more stages stepped as shown in the figure. The reversing turbine which is seen on the left-hand side in fig. 63, at the place where the rotor is reduced in diameter, has 26 stages in 4 steps. These turbines have a total normal horse power of 12,500, and run at 450 revolutions per minute.

128. *Longitudinal Forces in Marine Turbines.*—In a marine steam turbine the size of the dummy is reduced so that instead of balancing the whole steam thrust it leaves a resultant force which nearly balances the propeller thrust. Consequently only a small thrust block has to be provided to take any difference there may be between these forces. This thrust block is shown on the extreme right in each figure, beyond the gland and bearing. The dummy (at D in the figures) is made up of some 22 rings of brass fixed in the case in close proximity to the faces of projecting rings on the rotor (fig. 64) with a longitudinal clearance of 0·015 in. This form of dummy is suitable for the end near the thrust block, where exact longitudinal adjustment is possible, but the astern turbine in fig. 63

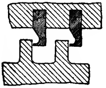

Fig. 64.

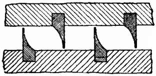

Fig. 65.

requires a different form because some longitudinal play is necessarily brought about there by differences in expansion of the rotor and stator. Accordingly, the astern dummy is of the "radial" form shown in fig. 65 where the fine clearance is round the circumference of the brass rings set in the rotor and stator alternately. The whole dummy includes about sixteen of these rings.

129. *Shaft Arrangement of Marine Turbines.*—Fig. 66 shows the usual three-shaft arrangement, with two low pressure turbines in parallel on the wing shafts, and one high pressure turbine, with which they are jointly in series, on the middle shaft. In very large vessels four shafts are used, and the turbines form two independent sets one on each side of the ship. The outer shaft on each side carries a high pressure turbine, and the inner shaft carries the corresponding low pressure turbine and also a turbine for reversing. This arrangement is followed in the "Lusitania" and "Mauretania" where the low pressure turbines have drums 188 in. in diameter, are about 17½ ft. in diameter over all and 50 ft. long, and weigh 300 tons. Each turbine has 8 steps with about 16 stages in each step in the high pressure turbine and 8 in the low. They run at 180 revolutions per minute.

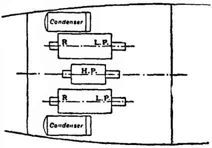

Fig. 66.

130. *Cruising Turbines in War-Ships.*—In turbines for the propulsion of war-ships it is necessary to secure a fairly high economy at speeds greatly short of those for which the turbines are designed when working at full power, for the normal cruising speed of such vessels is usually from half to two-thirds of the speed at full power. To counterbalance the reduced blade velocity, when running under these conditions, the number of rows of blades has in some cases

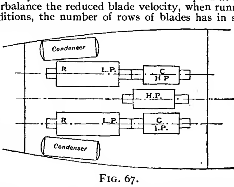

Fig. 67.

been augmented by adding what are called cruising turbines, which are connected in series with the main turbines when the ship is to run at cruising speed. In the three-shaft arrangement the cruising turbines are fitted on the wing propeller shafts, which carry also the low pressure and astern turbines. They form a high and intermediate pressure pair through which the steam may pass in series before going on to the main turbines. This arrangement is shown in fig. 67, where C.H.P. and C.I.P. are the two cruising turbines. In cruising at low speeds the whole group of turbines is used in series: when the speed is increased a larger amount of power is got by admitting steam direct to the second cruiser turbine; and finally at the highest speed both cruiser turbines are cut out. The arrangement shown in fig. 67 has been used in some torpedo-boat destroyers and small cruisers. In some large cruisers and battleships a four-shaft system is employed and a longitudinal bulkhead divides the whole group into two independent sets. On each of the outer shafts there is a high-pressure ahead and also a separate high-pressure astern turbine. On each of the inner shafts there is a combined low-pressure ahead and astern turbine and also a cruising turbine. All four shafts can be reversed.

131. *Application of Parsons Turbine.*—The Parsons was the earliest steam turbine to be made commercially successful, and it has found a wider range of application than any other. Its chief employment is as an electric generator and as a marine engine, but it has been put to a considerable number of other uses. One of these is to drive fans and blowers for exhausting air, or for delivering it under pressure. The turbine-driven fans and blowers designed by Mr Parsons are themselves compound turbines driven reversed in such a manner as to produce a cumulative difference in the pressure of the air that is to be impelled.

An interesting field for the application of steam turbines is to economize the use of steam in non-condensing engines of the older type, by turning their exhaust to the supply of a turbine provided with an efficient condenser. It is a characteristic of the turbine that it is able to make effective use of low pressure steam. No condensing piston and cylinder can compete with it in this respect; for the turbine continues to extract heat energy usefully when the pressure has fallen so low that frictional losses and the inconveniences attaching to excessive volume make it impracticable to continue expansion to any good purpose under a piston.

132. *Parsons Vacuum Augmenter.*—For the same reason it is especially important in the turbine to secure a good vacuum: any increase in condenser pressure during a turbine test at once shows its influence in making a marked reduction of steam economy. In the region of usual condenser pressures a difference of 1 in. changes the steam consumption by about 5%. With this in mind Mr Parsons has invented a device called a vacuum augmenter, shown in fig. 68. The condensed water

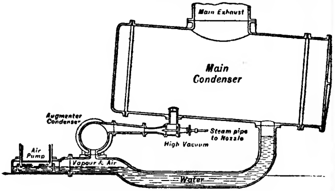

FIG. 68.—Parsons Vacuum Augmenter.

passes to the air-pump through a pipe bent to form a water-seal. The air from the condenser is extracted by means of a small steam jet pump which delivers it into an "augmenter condenser" in which the steam of this jet is condensed. The vacuum in the augmenter condenser is directly produced by the action of the air-pump. The effect of this device is to maintain in the main condenser a higher vacuum than that in the augmenter condenser, and consequently a higher vacuum than the air-pump by itself is competent to produce. This is done with a small expenditure of steam in the jet, but the effect of the augmented vacuum on the efficiency of the turbine is so beneficial that a considerable net gain results.

133. *Rateau and Zölly Turbines.*—Professor Rateau has designed a form of steam turbine which combines some of the features of the Parsons turbine with those of the De Laval. He divides the whole drop into some twelve or twenty-four stages and at each stage employs an impulse wheel substantially of the De Laval type, the steam passing from one stage to the next through a diaphragm with nozzles. This form can scarcely be called an independent type. It has been applied as an exhaust steam turbine in conjunction with a regenerative thermal accumulator which enables steam to be delivered steadily to the turbine although supplied from an intermittent source. The Zölly turbine, which has found considerable application on a large scale, acts in a precisely similar manner to that of Rateau: it differs only in mechanical details.

134. *Combined Reciprocating and Turbine Engines.*—The combination of a reciprocating engine with a turbine is suggested by Parsons for the propulsion of cargo or other low-speed steamers where the speed of the screw shafts cannot be made high enough to admit of a sufficient blade velocity for the efficient treatment in the turbine of high-pressure steam. With a small speed of revolution blade velocity can be got only by increasing the diameter of the spindle, and a point is soon reached when this not only involves an unduly large size and weight of turbine, but also makes the blades become so short (by augmenting the circumference of the annulus) that the leakage loss over the tips becomes excessive. This consideration confines the practical application of turbines to vessels whose speed is over say 15 knots. But by restricting the turbine to the lower part of the pressure range and using a piston and cylinder engine for the upper part a higher economy is possible than could be reached by the use of either form of engine alone, the turbine being specially well adapted to make the most of the final stages of expansion, whereas the ordinary reciprocating engine in such vessels makes little or no use of pressure below about 7 lb per sq. in.

135. *Consumption of Steam in the Parsons Turbine.*—In large sizes the Parsons turbine requires less steam per horse-power-hour than any form of reciprocating engine using steam under similar conditions. Trials made in April 1900, by the present writer, of a 2000 h.p. turbine coupled to an electric generator showed a consumption of $18\frac{1}{4}$ lb per kilowatt hour, with steam at 155 lb per sq. in. superheated 84° F. Since 1 kilowatt is 1·34 h.p. this consumption is equal to 13·6 lb per electrical horse-power-hour. The best piston engines when driving dynamos convert about 84% of their indicated power into electric power. Hence the above result is as good, in the relation of electric power to steam consumption, as would be got from a piston engine using only 11·4 lb of steam per indicated horse-power-hour. An important characteristic of the steam turbine is that it retains a high efficiency under comparatively light loads. The figures below illustrate this by giving the results of a series of trials of the same machine under various loads.

Load in kilowatts . . .	1450	1250	1000	750	500	250
Steam used per kilo-watt-hour in pounds	18·1	18·5	19·2	20·3	22·6	34·0

Still better results have been obtained in more recent examples, in turbines of greater power. A Parsons turbine, rated as of 3500 but working up to over 5000 kilowatts tested in 1907 at the Carville power station of the Newcastle-on-Tyne Electric Supply Company, showed a consumption of only 13·19 lb of steam per kilowatt-hour, with steam of 200 lb pressure by gauge and 67° C. superheat (temperature 264·7° C.), the vacuum being 29·04 in. (barometer 30 in.). It is interesting to compare this performance with the ideal amount of work obtainable per pound of steam, or in other words with the ideal "heat drop." At the temperature and pressure of supply the total heat I_1 is 709. After expansion to the pressure corresponding to the stated vacuum (0·96 in.) the total heat of the wet mixture would be 486, the dryness being then 0·792, if the expansion took place under ideal adiabatic conditions. Hence the heat drop $I_1 - I_2$ is 223 units, and this represents the work ideally obtainable under the actual conditions as to temperature and pressure of supply and exhaust. Since 1 kilowatt-hour is 1896 thermal units (lb—degree C.), each pound of steam was generating an amount of electrical energy equivalent to $\frac{1896}{13 \cdot 19}$ or 143·7 thermal units, and the electric output consequently corresponds to $64\frac{1}{2}$% of the ideal work. If we allow for the loss in the electric generator by taking the electrical output as 92% of the mechanical power, this implies that 70% of the ideal work in the steam was mechanically utilized.

136. *Torsion Meters for Power.*—No measurement corresponding to the "indicating" of a piston engine is possible with a

steam turbine. In the tests that have been quoted the useful output was determined by electrical means. Direct measurements of the useful mechanical power (the "brake" power) may, however, be obtained by applying a torsion dynamometer to the shaft. Devices are accordingly used in marine turbines for determining the horse-power from observations of the elastic twist in a portion of the propeller shaft as it revolves. In Denny & Johnson's torsion meter two light gun-metal wheels are fixed on the shaft as far apart as is practicable, generally 15 or 20 ft., and their relative angular displacement is found by comparing the inductive effects produced on fixed coils by magnets which are carried on the wheels. In Hopkinson & Thring's torsion meter a short length of shaft—a foot or so—suffices. A small mirror is carried by a collar fixed to the shaft, and a second collar fixed a little way along is geared to the mirror in such a way as to deflect the mirror to an extent proportional to the twist: the deflexion is read by means of a lamp and scale fixed alongside. As the shaft revolves the light reflected from the mirror is momentarily seen at each revolution and its position along the scale is easily read. (J. A. E.)

STEAMSHIP LINES. The shipping company is the outcome of the development of the steamship. In former days, when the packet ship was the mode of conveyance, there were combinations, such as the well-known Dramatic and Black Ball lines, but the ships which were run in them were not necessarily owned by those who organized the services. The advent of the steamship changed all that. It was in the year 1815 that the first steamship began to ply between the British ports of Liverpool and Glasgow. In 1826 the "United Kingdom," a "leviathan steamship," as she was considered at the time of her construction, was built for the London and Edinburgh trade, steamship facilities in the coasting trade being naturally of much greater relative importance in the days before railways. In the year 1823 the City of Dublin Steam Packet Company was inaugurated, though it was not incorporated till ten years later. The year 1824 saw the incorporation of the General Steam Navigation Company, which was intended not only to provide services in British waters, but also to develop trade with the continent. The St George Steam Navigation Company and the British & Irish Steam Packet Company soon followed. The former of these was crushed in the keen competition which ensued, but it did a great work in the development of ocean travelling. Isolated voyages by vessels fitted with steam engines had been made by the "Savannah" from the United States in 1819, and by the first "Royal William" from Canada in 1833, and the desirability of seriously attacking the problem of ocean navigation was apparent to the minds of shipping men in the three great British ports of London, Liverpool and Bristol. Three companies were almost simultaneously organized: the British & American Steam Navigation Company, which made the Thames its headquarters; the Atlantic Steamship Company of Liverpool; and the Great Western Steamship Company of Bristol. Each company set to work to build a wooden paddle steamer in its own port. The first to be launched was the "Great Western," which took the water in the Avon on the 19th of July 1837. On the 14th of October following the "Liverpool" was launched by Messrs Humble, Milcrest & Co., in the port from which she was named, and in May 1838 the Thames-built "British Queen" was successfully floated. The "Great Western" was the first to be made ready for sea.

But the rival ports were determined not to be deterred by delays in getting delivery of their specially built ships. The London company chartered the "Sirius," a 700-ton steamship, from the St George Steam Packet Company, and despatched her from London on the 28th of March 1838. She was thus the first to put to sea. She eventually left Cork on the 4th of April, and reached New York on the 22nd, after a passage of 17 days. The "Great Western" did not leave Bristol till the 8th of April, but under the command of James Hosken, R.N. (1798–1885) she reached New York only a few hours after the "Sirius." The Liverpool people, fired by the action of the other two ports, chartered the "Royal William" from the City of Dublin Steam Packet Company, and despatched her on the first steam voyage from the Mersey to Sandy Hook on the 5th of July in the same year. The "Liverpool" made her maiden voyage in the following October. But the "British Queen" did not make her initial attempt till the 1st of July 1839. Trouble overtook all three of these early Atlantic lines, and they soon ceased to exist.

Perhaps the most serious factor against them was the success of Mr Samuel Cunard in obtaining the government contract for the conveyance of the mails from Liverpool to Halifax and Boston, with a very large subsidy. The Cunard Line was enabled, and indeed, by the terms of its contract, obliged, to run a regular service with a fleet of four steamships identical in size, power and accommodation. It thus offered conveyance at well-ascertained times and by vessels of known speed. The other companies, with their small fleets of isolated ships and their irregular departures, could not continue the competition. The Atlantic Steamship Company of Liverpool found that the port could not then maintain two steamship lines, and the steamship "Liverpool," with another somewhat similar vessel which they had built, fell into the hands of the P. & O. Company. The Great Western Steamship Company proceeded to build the "Great Britain," an iron screw steamship, which in every way was before her time, and were swamped by financial difficulties, their "Great Western" being sold to the West India Royal Mail Company, to whom she became a very useful servant. The "Great Britain" (which was stranded in Dundrum Bay in September 1846, owing to her captain, Hosken, being misled by a faulty chart and mistaking the lights) eventually drifted into the Australian trade. The London company put a second ship, the "President," on their station. She was lost with all hands, no authentic information as to her end ever being obtained. Her mysterious fate settled the fortunes of her owners, and the "British Queen" was transferred to the Belgian flag. Steam navigation across the Atlantic was now an accomplished fact. But all the three pioneers had been borne down by the difficulties which attend the carrying out of new departures, even when the general principles are sound.

Constant improvement has been the watchword of the shipowner and the ship-builder, and every decade has seen the ships of its predecessor become obsolete. The mixed paddle and screw leviathan, the "Great Eastern," built in the late 'fifties, was so obviously before her time by some fifty years, and was so under-powered for her size, that she may be left out of our reckoning. Thus, to speak roughly, the 'fifties saw the iron screw replacing the wooden paddle steamer; the later 'sixties brought the compound engine, which effected so great an economy in fuel that the steamship, previously the conveyance of mails and passengers, began to compete with the sailing vessel in the carriage of cargo for long voyages; the 'seventies brought better accommodation for the passenger, with the midship saloon, improved state-rooms, and covered access to smoke-rooms and ladies' cabins; the early 'eighties saw steel replacing iron as the material for ship-building, and before the close of that decade the introduction of the twin-screw rendered break-downs at sea more remote than they had previously been, at the same time giving increased safety in another direction, from the fact that the duplication of machinery facilitated further subdivision of hulls. Now the masts of the huge liners in vogue were no longer useful for their primary purposes, and degenerated first into derrick props and finally into mere signal poles, while the introduction of boat decks gave more shelter to the promenades of the passengers and removed the navigators from the distractions of the social side. The provision of train-to-boat facilities at Liverpool and Southampton in the 'nineties did away with the inconveniences of the tender and the cab. The introduction of the turbine engine at the beginning of the 20th century gave further subdivision of machinery and increase of economy, whereby greater speed became possible and comfort was increased by the reduction of vibration. At the same time the introduction of submarine bell signalling tends to diminish the risk of stranding and collision, whilst wireless telegraphy not only destroys the isolation of the sea but tends to safety, as was seen by the way in which assistance was called out of the fog when the White Star liner "Republic" was sinking as the result of a collision off Martha's Vineyard (1909).

In the following pages some of the ships which first embodied these improvements are mentioned, a brief history of the principal lines is attempted, and reference is made to some of the milestones on the road of improvement.

Allan Line.—The story of the Allan Line is that of the enterprise of one family. Captain Alexander Allan, at the time of the Peninsular War, conveyed stores and cattle to Lisbon for Wellington's army. After 1815 he began to run his vessel between the Clyde and Canada, and as years went on he employed several vessels in the service. Till 1837 the ships ran from Greenock to Montreal, but in that year, after the Clyde was deepened, the ships went to Glasgow, as they have continued to do ever since. Captain Allan and his five sons devoted all their energies to the development of the Canadian trade, and for about forty years the line ran sailing ships only, which were greatly in request for the emigrant traffic. In 1852 the Canadian government requested tenders for a weekly mail service between Great Britain and Canada. That of Sir Hugh Allan of Montreal, one of Captain Allan's sons, was accepted, and the Canadian mail line of steamships came into existence. It may be noted that the Allan Line inaugurated steamers of the "spar-deck" type, *i.e.* with a clear promenade deck above the main deck. This measure of safety was taken as a lesson from the disastrous foundering of the Australian steamship "London" in the Bay of Biscay in the year 1866. The company may claim, too, that their steamship "Buenos Ayrean," built for them in the year 1879 by Messrs Denny of Dumbarton, was the first Atlantic steamship to be constructed of steel. As time went on the company's services were extended to various ports on the eastern shores of North America and in the river Plate; and London, as well as the two strongholds of Glasgow and Liverpool, was taken as a port of departure. In the course of its career it has absorbed the fleet of the old State Line of Glasgow and a great part of the fleet of the Royal Exchange Shipping Company and of the Hill Line. Included in the latter fleet were the first twin-screw steamers constructed for a British North Atlantic line. The "Virginian" and the "Victorian," built for the Allan Line in 1905, were the first transatlantic liners propelled by turbines. The principal ports served by the Allan Line are (in the United Kingdom) Glasgow, Londonderry, Belfast, Liverpool and London; from these their vessels ply to many places in North and South America, including Quebec, Montreal, St Johns (Newfoundland), Halifax, St John (New Brunswick), Portland, Boston, New York, Philadelphia, Baltimore, Montevideo, Buenos Aires and Rosario.

American Line.—Though the American Line, as now constituted, is of comparatively modern origin, it is the successor of several much older organizations. Of these the oldest is the Inman Line, last acquired by it. On the 16th of April 1850 an iron screw steamship of 1609 tons gross register left Glasgow on her maiden trip to New York. This was the beginning of the Inman Line. After a few voyages this ship was sold to Messrs Richardson, Spence & Co. of Liverpool, in which William Inman (1825–1881) was a partner, and the sailings of the steamships were thenceforth for some years between Liverpool and Philadelphia. But in 1857 New York took the place of Philadelphia as a regular terminus. In 1859 the regular call at Queenstown was commenced by this line, which may be said to have been responsible for two other innovations in transatlantic traffic. Before 1850 practically all the steamships crossing the ocean, with the famous exception of the "Great Britain," were paddle-boats. After the advent of the Inman liners the screw began to be everywhere substituted for the paddle. In the second place, the Inman steamers were the first which regularly undertook the conveyance of third-class passengers, to the extinction of the old clipper vessels which had hitherto carried on the traffic. In 1867 the Inman liner "City of Paris" (the first bearing the name) held the westward record with 8 days 4 hours, and in 1869 the "City of Brussels" came home in 7 days 22 hours 3 minutes. Till 1872 these records held good. The "City of Brussels" also had the distinction of being the first Atlantic mail steamer to be fitted with steam steering-gear. About 1875 Mr William Inman turned the concern into a limited company, and in 1886 the business was amalgamated with the International Company, and the vessels, though still flying the red ensign, became the property of a group of United States capitalists, who also acquired the old American Line which had been started in 1873 with four Philadelphia-built steamers. This company had been conducted under the auspices of the Pennsylvania Railroad. It plied between Liverpool and Philadelphia. A third constituent in the Inman and International Steamship Company was the Red Star Line, as the Société Anonyme Belge-Americaine was familiarly called. Its service was from Antwerp to New York. The whole was placed under the management of Messrs Richardson, Spence & Co., who thus after thirty-two years reassumed the direction of the old company. In 1887 the two ships "City of New York" and "City of Paris" were built on the Clyde for the company. At the time of their construction they were the largest vessels ever built, always excepting the "Great Eastern." The "City of Paris" was the first vessel (1889) to cross the Atlantic in less than six days. The year 1893 was an important one in the history of the company, and indeed of the United States. The two vessels above mentioned were admitted to American registry by Congress, a stipulation being made that two new ships of at least equal tonnage and speed to the pair should be ordered by the company from American firms, and that they should be capable of being employed by the United States government as auxiliary cruisers in case of war. The American flag was hoisted over the "New York" in 1893 by President Harrison, and in the same year the British headquarters of the company were transferred from Liverpool to Southampton. In 1894 the first American-built ocean liner of the new fleet was launched, and was named the "St Louis." In 1898 the American Line had the distinction of supplying the navy of its country with cruisers for use in war. The "St Paul," the only vessel of the four under contract in American waters at the time, was put under the command of Captain Sigsbee, whose own battleship, the "Maine," had been blown up in Havana harbour on the 15th of February. The other three ships were also put into commission, the "Paris" being temporarily renamed the "Yale" and the "New York" the "Harvard." In 1902 with their twin-screw liner "Kensington" the American Line made the first experiments towards fitting Atlantic passenger steamers with appliances for the use of liquid fuel. The express fleet of the line consists of the four vessels, "St Louis" and "St Paul," each of 11,600 tons and a length of 554 ft.; and the "New York" and "Philadelphia," each of 10,800 tons and 560 ft. length. Several still larger but less speedy steamships have been constructed for the intermediate services of the company In addition to the weekly express service between Southampton and New York, the American Line runs steamers between New York and Antwerp, Philadelphia, Queenstown and Liverpool, and Philadelphia and Antwerp.

Austrian Lloyd Steam Navigation Company.—This company was started in 1837 at Trieste, where its headquarters are still situated. It commenced operations with seven small wooden paddle-boats for the voyage to Constantinople and the Levant. By 1910 they had increased to a fleet of sixty-two iron and steel steamships, with a gross tonnage of about a quarter of a million tons. The whole eastern coast of the Adriatic and the Levant is visited by them with frequent services. There is a line to the west as far as Brazil, and a monthly mail service between Trieste, Brindisi and Bombay. There is also a monthly ordinary service between Trieste, Bombay, China and Japan, and a monthly branch in connexion with it between Colombo, Madras and Calcutta.

Bibby Line.—The name of Bibby has long been known and respected in the shipping world. The first undertaking of the family was the institution of a service from Liverpool to Mediterranean ports about the middle of last century. When Mr (subsequently Sir Edward) Harland took over the ship-building works at Belfast, which he afterwards made famous, Mr Bibby was one of his earliest customers. It was he who gave him practically *carte blanche* in the way of proportion for the new ships built for his service, and it was from the experience acquired and the success achieved with them that the "long ships," with which the White Star Line made its name, were first brought into the region of the practical. In this connexion it may be stated that Sir Edward Harland was born at Scarborough in 1831, his father being a medical practitioner. He learnt the science of ship-building in the yards of Messrs R. Stephenson & Co. of Newcastle, and became first a draughtsman with Messrs J. & G. Thomson, and then manager in a Newcastle yard. In 1854 he went to Belfast, first as manager to Messrs Robert Hickson & Co. Then in 1858 he took over their yard. In 1859 he launched the "Venetian" for Mr Bibby, and in 1860 he took Mr G. W. Wolff into partnership. After a time Mr Bibby retired from the active pursuit of his business, and the line passed into the hands of one of his confidential managers—Mr Leyland (see *Leyland Line*). But the Bibby family, though large shareholders in the White Star Line, could not remain without some active interest in seafaring matters. Hence a new Bibby Line was started. Its first vessel was the "Lancashire," a single-screw steamer of 4244 tons gross register, built—as have been all this fleet—by Messrs Harland & Wolff. She came out in 1889. Her sister was a similar vessel. Subsequent additions to the fleet were all of the twin-screw type; thus the Bibby Line can boast that it was the first to maintain its service, which is now fortnightly, exclusively with twin-screw vessels. In the trade between Liverpool and Rangoon they soon made a name.

The Booth Line is essentially a Liverpool company. It was founded in the year 1866 by Messrs Alfred Booth & Co., who in that year instituted a service to north Brazil. Three years later from the same port was started the Red Cross Line of Messrs R. Singlehurst & Co. to carry on a similar service. In 1901 the two lines were amalgamated under the title of the Booth Steamship Company Limited. Since the year 1882 there has been a connexion by the Booth steamers between north Brazil and New York. Para, Manaos, Maranham, Paranahyba and Ceara are the chief Brazilian ports served by the company, whilst the steamers make calls on the eastern side of the Atlantic at Cardiff and Havre as well as at Spanish and Portuguese ports. The company carries the British mails to Para and Manaos, whilst it also takes the United States mails between New York and north Brazil. In addition to its transatlantic passenger traffic the Booth Line is largely developing a tourist trade to Vigo, Oporto and Lisbon in the Peninsula as well as to Madeira. The Yquitos Steamship Company, which is under its management, carries its trade a couple of thousand miles up the River Amazon; a further development will extend to River Plate ports.

British India Steam Navigation Company.—This line maintains, perhaps, a larger network of communications and serves a greater number of ports difficult of access than any in the world. The Persian Gulf, Burma, the Straits of Malacca, and the entire littoral of the East Indies, to say nothing of the east coast of Africa, are among the scenes of its enterprise. Though its ramifications now extend to the ports of northern Australia, the company had its origin in the Indian coasting trade. Its present designation is of comparatively recent origin, but its first operations date from 1855. A project for a mail service between Calcutta and Burma was then first set on foot by the East India Company. Early in the following year a company was formed, under the title of the Calcutta and Burma Steam Navigation Company. Two small steamers of 600 tons each were brought and despatched to India round the Cape in 1857, for a service between Calcutta, Akyab, Rangoon and Moulmein, under a contract with the government of India. At the outbreak of the Mutiny in 1857 the company rendered important service by bringing up from Ceylon to Calcutta the first detachment of European troops which came to the assistance of India from outside. In 1862 an agreement was made between the company and the government, by which the former agreed to convey troops and stores and to perform other services. Under this arrangement steamers were to be despatched regularly from Calcutta to Rangoon, Moulmein, Akyab and Singapore, and from Rangoon to the Andaman Islands. A service was also set on foot to the Persian Gulf, between Bombay and Karachi and Madras and Rangoon. This gave a great impulse to the business of the company. During the Abyssinian campaign of 1867 it proved of the greatest assistance to the government. The opening of the Suez Canal in 1869 produced an entire revolution in the shipping trade of India, and led to a great development of the company's fleet. The s.s. "India" with cargo was waiting at Suez when the canal was opened to traffic, and was the first steamer to arrive in London through the canal with an Indian cargo. In 1872 the company extended its operations to the east coast of Africa, and by an arrangement with the British government began to run a service every four weeks between Aden and Zanzibar. Upwards of one hundred ports are visited by the company's steamers. In all there are twenty-one lines with additional services. They may be classed roughly as those running to ports in (i.) India, Burma and Straits Settlements; (ii.) Straits Settlements and Philippines; (iii.) East Coast of Africa; (iv.) Persian Gulf; (v.) Dutch East Indies and Queensland.

The Canadian Pacific Railway is now one of the big shipping companies of the world, owning, as it does, just under 200,000 tons of steam shipping. Its services divide themselves into several sections. There are those in home waters, such as the Great Lakes, where it employs a fleet of vessels of quite considerable tonnage. Under this head, too, come the local services on the coasts and rivers of the Pacific. Then there are the ocean lines on the Pacific and the Atlantic. The first of these is run from Vancouver via Yokohama and other Japanese ports to Hong-Kong. Sailings are made at about three-weekly intervals. This service is maintained by the three Empresses, the "Empress of India," the "Empress of China" and the "Empress of Japan," sister ships of about 6000 tons and 10,000 i.h.p., specially built with a view to serve as auxiliary cruisers to the British navy in time of war. The great development of the Canadian Pacific, as far as regards ship-owning, took place in 1903, when it took over from Messrs Elder, Dempster & Co. their transatlantic services to Canada. The "deal" affected four twin-screw passenger and cargo steamers, and some ten vessels of a purely cargo type. These steamers ranged in size from the "Monmouth," of just over 4000 tons gross register, to the "Lake Manitoba" of not far short of 10,000 tons. Since their entry into the Atlantic trade the company has added two important mail steamers—the "Empress of Britain" and "Empress of Ireland"—to that side of its fleet.

Castle Line (see also *Union Line* and *Union-Castle Line*).—The Castle Line began its career in 1872 with the "Iceland" and the "Gothland," both vessels of about 1400 tons. At that time the charge for carrying letters to the Cape was about 1s. per half oz., and the contract time between England and the Cape thirty-seven days. The mail contracts were then in the hands of the Union Line exclusively, but in 1873 the House of Commons refused to ratify the extension of the contract signed with them by the chancellor of the exchequer, and their rights thus expired in 1876. Up to 1876 the Cape parliament made an allowance to the Castle Line for the conveyance of letters, and when the postal contract was renewed in that year it was divided between the Union and the Castle lines, an arrangement which was adhered to down to the time when the two lines united their fortunes. The scope of the company's energies has now been extended to all parts of South Africa. The line did great national service in carrying troops and stores to South Africa during the 1899–1902 and previous campaigns. By a resolution passed at a meeting of shareholders held on the 13th of February 1900 this company was amalgamated with the Union Line. The fleet had grown from two ships in 1876 to twenty ships in 1900, and from a total tonnage of 2800 to one of about 110,000 gross register.

City of Dublin Steam Packet Company.—Among the steamship services in the narrow seas round Great Britain a special interest attaches to this company, which vies with the General Steam Navigation Company in the claim for seniority. The General Steam was undoubtedly the first to receive incorporation in the year 1824, but the undertakings from which the City of Dublin Company sprang were at work in the years immediately prior to these dates. As far as appears, the firm of Bourne & Co.—who fulfilled in Ireland functions for which the Messageries Impériales in France were first formed—were large shareholders in two undertakings which made history in regard to the development of steam navigation. One of these companies was the Dublin & London Steam Packet Company, from which Messrs Wilcox & Anderson, the first managers of the P. & O., chartered the "Royal Tar," the first steamer they despatched to the Peninsula, and the other was the City of Dublin Company, which originally occupied itself in the maintenance of a service of steamships between Dublin and Liverpool. It was this company's "Royal William" which had the distinction of opening the Liverpool service to New York. By absorption, too, this company represents the old St George Company, whose "Sirius" was the first steamer to sail from London towards New York. In the year 1838 the admiralty, which in those days had the management of many of the mail services and continued for a time to keep the Irish day mails in its own hands, gave the City of Dublin Company the contract for the night Irish mails, which were thus despatched via Liverpool. The name of Laird is to this day closely associated with the fortunes of the company, and even at that time a Mr Laird, grandfather of the present partners in the ship-building firm, was a director of the City of Dublin Company. In the year 1848 the government with four steamers endeavoured to run the day and night mails itself via Holyhead. But this arrangement did not work well, and two of its mail steamers were bought by the City of Dublin Company, while the two others were acquired by the Chester & Holyhead railway. It is needless to follow the vicissitudes of the mail service, wavering as it did from the admiralty to the Chester & Holyhead railway, and then to the City of Dublin Company. Suffice it to say that in 1859 an arrangement was entered into whereby the City of Dublin Company undertook the conveyance of both day and night mails via Holyhead, and built four ships, called after the four Irish provinces, for the service. The performances of these four paddle-ships, three of which were built by Messrs Laird, were remarkable indeed. The "Connaught" was the first vessel to do her 18 knots. The "Ulster" made the best passage of them all—doing the journey from Holyhead and Kingston in 3 hours 18 minutes. But the "Leinster" was only two minutes behind her, and the "Munster" only six minutes worse than the "Leinster." Taking the performances of the whole four vessels over the first fourteen years of their existence, and considering the mean of 20,440 passages made as well in winter as in summer, the average time of passage was only 3 hours 56·1 minutes. The contract was renewed from time to time, that coming into operation on the 1st of October 1883 being for an accelerated service. To enable this to be adequately performed, the last paddle-ship of the fleet, the "Ireland," was built by Messrs Laird, who also overhauled and improved the machinery of the older vessels, giving them new boilers adapted for the use of forced draught. In 1895 it was felt that the mode of carrying these important mails again needed revision, and in that year the House of Commons approved of a new contract, under which four new twin-screw vessels were to be built for the service. The work of design and construction was again undertaken by Messrs Laird, and in 1897 the new fleet assumed the duties, and indeed the names, of the vessels which had done such remarkable service during a period of about thirty-eight years. The contract time was now decreased by half an hour, and this meant naturally a very great increase in the speed of the vessels employed. The present ships, capable of a speed of about 24 knots, maintain however with regularity and ease the 20 to 21 knots which are required. Besides the night and day services with the mails the company also maintains its old line between Liverpool and Dublin.

Compagnie Générale Transatlantique.—A French undertaking known as the Compagnie Générale Maritime was founded in 1855. It owed its inception to the brothers Emile and Isaac Pereire. Services were first organized from Rouen to Algeria, between Havre and Hamburg, and between Marseilles and Antwerp, with calls at Spanish and Portuguese ports. In 1861 the company was allowed to change its title to the more comprehensive one under which it is now known, and it then undertook its first contracts for the carriage of the French mails to the United States, the Antilles and Mexico. Some of the earlier vessels employed in the New York service were very fine specimens of the naval architecture of their day. Among them may be instanced the great iron paddle-steamer "Napoleon III.," built in the year 1864 by Messrs Scott & Co. of Greenock, who at that time constructed most of the more important vessels for this service. This vessel with her imperially titled sisters suffered a change of name in the early 'seventies, when several of them were lengthened and altered to screws. In the year 1881, again, there was a great movement towards the acceleration and improvement of the New York service, and a new fleet was begun with the single-screw steamship "La Normandie," launched at Barrow-in-Furness in 1883. Four larger vessels of much the same class followed, three of them being constructed in the owners' own yard at Penhoet. In 1890 the first twin-screw steamer of the line appeared in "La Touraine," and proving a success, the British-built "L'Aquitaine" was purchased. A new postal contract was arranged in 1898, and under its terms it became necessary for the company to build still larger and faster vessels. Eventually four such ships were to be provided. These vessels are of 22 knots speed on trial, and are among the fastest on the Atlantic. The company maintains a weekly service to New York, as well as the lines to the Antilles and Mexico in the Atlantic. There are also communications with British and Algerian ports.

Cunard Line.—This company derives its name from Samuel Cunard of Halifax, Nova Scotia, an owner of sailing vessels trading from Boston and Newfoundland to Bermuda. He first conceived the idea of a regular despatch of royal mail steamships across the Atlantic, to take the place of the government brigs, which often took six or seven weeks in the transport of mails. This idea he realized with the help of Mr George Burns of Glasgow and Mr David MacIver of Liverpool. On the 4th of July 1840 the first Cunarder, the "Britannia," started on her voyage across the Atlantic with sixty-three passengers, landing them at Boston in a fortnight. The experiment of using the screw for the Atlantic service was made with several cargo steamers in the early 'fifties, and the first Cunard screw steamer for the mail line made her début in 1862. This was the "China," the gross tonnage of which was 2539, her i.h.p. 2250, and her average speed 13·9 knots. In 1870 the Cunard Company first fitted compound engines to their steamship "Batavia," and in 1881 the "Servia," the first steel vessel in the service, was the pioneer of the larger type which constitutes the present express fleet. Since 1840 the Cunard Company has been under contract with the British government for a mail service. At the present time the contract is for a weekly mail to the United States, via Liverpool and New York. The British post office, however, only pays its contractors for the weight of mails actually carried, and reserves the right to send specially addressed letters by foreign ships. The company's services also include a passenger line to Boston, and frequent despatches to Mediterranean and Levant ports as well as a weekly steamer to Havre, and a passenger service from the Mediterranean to New York. In October 1902, as a result of the formation of the Morgan Shipping Trust, the British government made a new arrangement with the Cunard Line, involving the loan at 2¾% of the capital for building two new fast steamers, besides a yearly subsidy of £150,000 for twenty years. The company showed its confidence in the turbine system—then in its infancy—by adopting this principle for these two vessels, the largest and fastest at that time contemplated. The advance in size and power of Atlantic steamships is evidenced by the following comparison:—

		Speed.	Tonnage.	H.P.
1884	"Umbria" and "Etruria" .	19	8,127	14,500
1893	"Campania" and "Lucania" .	22	12,952	30,000
1907	"Lusitania" and "Mauritania"	25	30,830	68,000

Elder, Dempster & Co.—The remarkable progress of this company, and of the undertakings connected with it, was largely due to the activity of the late Sir Alfred Jones. The oldest business under its management is the African Steamship Company, which was incorporated by royal charter in the year 1852 for the purpose of trading with West African ports. It received a subvention of £30,000 per annum for a monthly mail to the Gold Coast, and began its work with an unambitious little fleet of four 700-ton vessels. These were at first, however, equal to all the traffic which the trade could offer them. As time went on the number and size of the vessels employed was increased. In 1869 such progress had been made that it appeared worth while to start an opposition line under the name of the British and African Steam Navigation Company. This was at first a Glasgow venture, much in the same way as the old concern had made its headquarters in London. But Liverpool has long been the centre of the West African trade, and both companies practically transferred their business thither. In the year 1883 the British & African Company, which was the first of the two to fall under the management of Messrs Elder, Dempster & Company, became a limited company, and not long afterwards the two rivals arrived at a working arrangement whereby their sailings—at that time about three times a fortnight—were worked into one another. The Canary Islands, where the West African steamers called on their voyages, were then becoming known as a resort for tourists and invalids, and the issue of tickets available by either line was commenced for their convenience. The development of the cultivation of the banana for the English market was also begun to be encouraged by the two steamship companies. But it was in the month of August 1891 that the great movement by the Elder-Dempster Company was made public. It was then announced that the firm had assumed the management of the African Company. The two concerns were, and are, continued as distinct organizations, but they naturally work very closely together. The African Company soon began to break fresh ground, building not only superior vessels for the improving West African service, but also constructing large cargo vessels for the general Atlantic trade. These were soon engaged in the trade between the Mersey and the St Lawrence on the one hand, and between Liverpool and the southern ports of the United States on the other. Meanwhile the development of the possibilities of West Africa and of the Canary Islands was not neglected. Various undertakings, not usually considered part of a shipowner's work, were inaugurated. These included a bank, founded in 1894, for the accommodation of West African traders, oil-mills in Liverpool, where the palm kernels so largely consigned from the coast might be dealt with, and a hotel at Grand Canary for the convenience of the tourist; while, to ensure the disposal of the bananas which their companies brought to England, a fruit brokerage business was opened in Covent Garden. Having already, as has been seen, a footing in the Canadian trade, they began the restoration of the Atlantic trade to Bristol, by giving it a service of steamships to the St Lawrence, employing for the purpose vessels of as great size as their docks could accommodate. At the beginning of 1899 they further strengthened their connexion with the nearest British colony by the purchase, from the liquidator of the insolvent Canada Shipping Company, of the name, house-flag and remains of the old Beaver Line. A new fleet for this service was at once put in hand, a fair representative of the ships being the twin-screw "Lake Erie," a vessel of 7550 tons gross register, built in 1900 by Messrs Barclay, Curle & Co. of Glasgow, which did good work—with many other Elder-Dempster steamers—in the transport service during the Boer War. The Canadian steamers were however in 1903 transferred to the Canadian Pacific railway. At the beginning of the 20th century the firm began trading with the West Indies. By arrangement with the colonial office, for an annual subsidy of £40,000, the "Direct" service of fortnightly steamships was started with the sailing from Avonmouth of the then newly built "Port Morant" in February 1901. The steamships of the new line have good passenger accommodation and hotels were acquired in Jamaica to provide accommodation for those who wished to visit the West Indies under the new management. This provision for tourists was a novel feature. The increase, at once absolute and comparative, in the tonnage of the Elder-Dempster fleet has been very remarkable. On the death of Sir Alfred Jones a limited company was established under the direction of Lord Pirrie, of the great ship-building firm of Harland & Wolff, and of Sir Owen Philipps, chairman of the Royal Mail Steam Packet Company, to carry on the Elder-Dempster Company and take over the various interests concerned. The vessels of the West African lines ply as well from Hamburg and other North Sea continental ports as from Liverpool, while closely connected with the firm, though sailing its vessels under the Belgian flag, is the Compagnie Belge Maritime du Congo, which runs a service from Antwerp to West African ports.

Ellerman Line.—"Lloyd's Register of Shipping" in its issue for 1901–1902 contains no reference to the Ellerman Line. For unlike most other shipping companies it sprang into being in a moment. It was started when Mr (afterwards Sir) John Ellerman, chairman of the Leyland Line, severed his connexion with that company and went his own way, taking with him some nineteen vessels of the fleet, and the Peninsula and Mediterranean connexions of the old company. Forthwith he added to the tale of his ships by taking over the management of the seven steamers of the Papayanni Line—which has also long maintained a service to Mediterranean ports. Nine steamers previously managed by Messrs Westcott & Laurence also came into the fold. But this was not all; the direction of two old-established lines to Indian ports was also acquired. These were the fleet of the City Line, which at that time comprised some fifteen vessels, many of them fitted for the passenger trade. This line had been founded by Messrs George Smith & Sons of Glasgow in the first half of the 19th century and had grown up out of a fleet of sailing vessels. The other was the Hall Line of Liverpool, previously managed by Messrs Robert Alexander & Co. It consisted of some eleven steamships of about 4000 tons gross apiece. The various sailings of these different companies have all been maintained and extended, and in 1910, in conjunction with the Harrison and Clan lines, a new development up the East Coast of Africa towards Zanzibar and Mombasa was organized.

The Leyland Line may be said to date from the year 1851, when the first Mr Bibby founded his steamship line with the small vessels "Arno" and "Tiber" for service to the Mediterranean (see *Bibby Line* above). The company extended its business to the North Atlantic and in the early 'seventies changed its name, Mr F. R. Leyland, one of its managers, assuming the control. On his death in 1892 the concern became a limited company. In 1900 it purchased the fleet and connexions of the West India & Pacific Steamship Company—a business which had been founded nearly forty years previously in Liverpool and which served, beside many West

India Islands, the cotton ports of Galveston and New Orleans, having also a connexion to Colon for places on the western coast of America. This company at the date of its absorption had a fleet of twenty-two steamships totalling over 111,000 tons gross register. This amalgamation was the first step towards the great American combine. Mr Ellerman, however, who was chairman of the old Leyland Company, separated himself from it at this juncture, and founded his own line. The Leyland Company had a number of transatlantic services.

General Steam Navigation Company.—This is the oldest existing line. Its first prospectus was issued in 1824, and in 1831 it received its charter of incorporation. It commenced with the passenger trade from London to Margate, and its operations gradually extended to the British coastwise ports and the home trade ports on the Continent. In time the company introduced a regular steam service between Edinburgh and other east coast ports and London, Hamburg, Rotterdam, Antwerp and Havre in the north of Europe. It gradually obtained a strong hold upon the passenger and fine goods trade to the Continent, holding the mail contracts between London and Hamburg, and London and Rotterdam. In the early 'seventies the pressure of foreign competition made itself severely felt, and in 1876 the increase of the American cattle trade told on the profits of the company; but the difficulty was met by obtaining parliamentary leave for an increase of capital, and the company had displayed new enterprise, especially in regard to its passenger facilities. It may claim to have been the pioneer in the promotion of steamship traffic between British home ports and the nearer ones of the Continent. The steamship "Giraffe," built in 1836, brought over the first cargo of live cattle from Rotterdam to Blackwall in 1846. The company runs steamers from London to Edinburgh, Hull and Yarmouth, and from London to Antwerp, Amsterdam, Bordeaux, Havre, Hamburg, Oporto, Ostend, Rotterdam, Charente and the Mediterranean ports. Vessels are also run to some of the ports above-named from Hull and Southampton. There is also a passenger service between Harwich and Hamburg, and excursion services in summer to the watering-places at the mouth of the Thames and on the Kentish coast.

Hamburg-American Line.—The extraordinary progress of Hamburg as a seaport during the last thirty years of the 19th century may be held due in no small measure to the enterprise of this line, which now carries passengers not only to the two American continents, but also to the east of Asia and Africa. It was founded in May 1847. At that time, owing to the political disturbances throughout Germany, there was an enormous exodus of emigrants to the new world; of this the founders took advantage, and they started a regular service of sailing ships between Hamburg and New York. The first ship they owned was the "Deutschland," of 700 tons, built on the Elbe. It is interesting to note that the present "Deutschland" is of 16,502 tons gross register, and is of twenty-three times the capacity of her predecessor. The first sailing took place in October 1848. In 1851 the company's fleet consisted of six vessels, with an aggregate of 4000 tons. In 1856 the first screw steamer in the company's service left Hamburg; this was the "Borussia," a vessel constructed, as were her sisters for many years, on the Clyde. From this time, when the company abandoned sailing ships and took to steam, its prosperity may be said to have dated. It is strange to note that the two first steamships owned by it were chartered by the British and French governments to convey troops to the Crimea. By 1867 the company had ceased to own any sailing ships. The enormous increase of the traffic is indicated by the fact that whilst in 1856 the sailings to New York took place every fortnight, in 1881 there were two a week, and later on three. The company had also by this time considerably extended its operations from the original passage between Hamburg and New York. After the war between France and Germany it started a line to the West Indies, and later to Baltimore, Boston, Montreal and other ports in North America. In 1875 it absorbed the old Eagle Company of Hamburg, which had previously been its rival, and then began to run steamers to Central and South America, and later to China, Japan and the Straits Settlements. To-day the Hamburg-American Line may claim to be the largest steamship company in the world. For its services to New York run by twin-screw steamers it has the "Deutschland," built at Stettin by the Vulcan Company. Her engines develop about 33,000 horse-power, and she was the first Atlantic liner to exceed a speed of 23 knots at sea. Other large steamers built for its Hamburg-Southampton-New York service are the "Kaiserin Augusta Victoria" and the "Amerika," which, though larger, has not the "Deutschland's" speed. A service from Hamburg to New York direct for third-class passengers only is also maintained. The Hamburg Company has extended its influence and enlarged its fleet by purchases from and absorptions of other fleets. Thus it has acquired vessels from the Carr Line and the Hansa Line of Hamburg, the Rickmers Line of Bremen, as well as from the Hamburg South America and the Hamburg-Calcutta companies. In conjunction with the Lloyd Line it took over the fleet of the Kinsing Line. In 1901, with a view to the feeding of its main lines, it acquired the Atlas Line of Liverpool—a company which had developed the trade between New York and the West Indies. Starting from Hamburg, its vessels run to New York, Portland, Baltimore, Boston, Philadelphia, Galveston and New Orleans, and to Canadian ports. In Central and Southern America, there are lines to Mexico, Venezuela, Brazil, Uruguay and Argentina. Amongst the West Indian Islands Cuba receives special attention from this line. There is a service to Eastern Asia, China and Japan. From Stettin its steamers run to New York, and from New York to the Mediterranean, Brazil and Eastern Asia. From Genoa they run to La Plata direct.

Japan Mail Steamship Company, Limited (Nippon Yusen Kaisha).—From an early period their insular frontiers made the Japanese a seafaring folk, but imperial policy for a long period shut them away from all intercourse with the rest of the world. It was not until about the year 1860 that the life of the West really touched Japan. In 1868 steamship communication was opened between Tōkyō and Osaka; in 1871 the Yubin Kisen Kaisha Steamship Company came into existence under the control of the Imperial Bureau of Communication; and in the same year a private company, called the Mitsubishi Kaisha, was founded. This may be said to have been the beginning of all modern maritime enterprises in Japan. In 1876 the government company gave up the contest, and its fleet passed into the hands of the private company. In 1873 the capacities of this company had been tested in the military expedition to Formosa, when its organization had been found excellent, but its fleet insufficient. The treasury now invited the company to buy up the Yokohama-Shanghai service of the Pacific Mail Steamship Company. In 1876 the company had a fleet of forty-two vessels, including sailing ships. In 1882 the government set on foot another rival line, the Kyodo Unyu Kaisha, but it did not answer, and in 1885 the two were amalgamated into the present "Nippon Yusen Kaisha," or "Japan Mail Steamship Company." In the nine years which passed between this union and the outbreak of the war with China in 1894, the services between Japan and neighbouring countries were extended, and the development of the cotton trade induced the government to inaugurate a service between Japan and Bombay. During the war the vessels of the line were used for the transport of troops, and many additional ships had to be acquired. The result of the war gave an enormous impulse to trade and navigation. The company determined to run vessels to America, Europe and Australia. The capital was greatly increased, and orders were given for the construction of twelve twin-screw steamers of over 6000 tons each for the European line, and three of 3800 tons each for the Australian line. In 1899 the Japanese Diet resolved to grant subsidies to the company's European and American lines. All its lines therefore now, with few exceptions, run under the mail contract of the Japanese government. There is a regular fortnightly service of twin-screw vessels between Yokohama, London and Antwerp; a monthly service between Yokohama and Melbourne; also between Yokohama and Victoria (British Columbia). There are lines to Bombay, Shanghai, Vladivostok, Newchang, Tientsin, and many local lines, touching at all the ports of the islands of Japan.

Royal Mail Steam Packet Company.—Soon after British-owned steamships began to run to America a company was formed by leading business men interested in the West Indies, to carry the mails from England to that part of the world. The charter of this company, to be known as the Royal Mail Steam Packet Company, was granted in 1839. The government believed that the institution of a line carrying the mails regularly to British possessions in the West Indies was likely to prove of benefit to the empire, and granted it a large subsidy. The first contract with the government was entered into in March 1841. No less than fourteen large paddle-steamers capable of carrying the largest guns then used by the Royal Navy were at once ordered, and the service was opened with the "Thames" on the 3rd of January 1842, followed by other vessels in fortnightly succession. These steamers started from Falmouth and returned to Southampton, which was the company's headquarters, though it had no dock accommodation in those days. In 1846 the company began to carry the mails for places on the western coast of South America, the Pacific Steam Navigation Company receiving them at Panama. In January 1851, the company by contract with the government inaugurated a monthly service to Brazil and the river Plate, and new steamers were built which greatly increased the rapidity of transit. This company was therefore the first to institute direct mail communication by steamer between Europe and the countries of South America, as it had also been with the West Indies. The company's vessels were employed continuously during the Crimean War in the transport of troops. It is interesting to note that it was from one of the company's ships, the "Trent," that Slidell and Mason, the commissioners of the Confederate states, were taken on their way to Europe by a United States man-of-war. In 1872 the service to Brazil and the River Plate was doubled. At the beginning of the 20th century the company seemed to be on the downward grade. But a change came over its fortunes. A new chairman, Sir Owen Philipps, took over the reins and new enterprises were started in several directions. The interest of the Pacific Steam Navigation Company in the Orient-Pacific Line to Australia was purchased in January 1906, and steamers despatched once a month from London to Australia through the Suez Canal. This enterprise, however, was discontinued when the new mail contract came into force in May

1909. New twin-screw steamships of much greater tonnage than any they had hithertofore owned were constructed for the mail service to South America, and an extension was made into the tourist and cargo trade to Morocco, Madeira and the Canary Islands by the purchase of the old-established Forwood Line. Part of the fleet of the Shire Line to the Far East was also acquired. But the great development took place at the beginning of 1910, when the directors made the startling announcement that they had purchased the whole of the share capital of the Pacific Steam Navigation Company—a business established in Liverpool only a year after the grant of their own royal charter. This absorption brought some forty ships—many of them modern twin-screw steamships of a high class—into the fleet, which was then placed amongst the big lines of the world. Another move was made when Sir Owen Philipps joined Lord Pirrie in organizing a company to take over the numerous enterprises of Sir Alfred Jones. The West India Line steamers leave Southampton for the West Indies every fortnight, and after calling at Cherbourg proceed direct to Barbadoes, thence to Jamaica and Colon, whence they proceed to Savanilla and other local ports. From Barbadoes, Trinidad, La Guaira, branch lines run to Demerara and the islands. The Brazil and River Plate Line comprises a fortnightly service of mail steamers to Pernambuco, Bahia, Rio, Montevideo and Buenos Aires. The Shire Line steamers sail to the Far East every fortnight, as do those of the Islands service, whilst the Pacific Line despatches twin-screw passenger steamers and large cargo vessels alternate weeks from Liverpool to South American ports, besides maintaining local services up the West Coast. There are also cargo services to the West Indies and Mexico, and to the River Plate and intermediate ports.

Messageries Maritimes de France.—Originally known as the Messageries Impériales, this company sprang from a land-transit undertaking. It received its first contract for the conveyance of oversea mails from the French government in 1851. It then extended its services to Italian, Greek, Egyptian and Syrian ports. In the following year it included Salonica in its itinerary. The occurrence of the Crimean War gave an increase to its fleet and a stimulus to its operations. For it was not only given the task of maintaining mail communication with the French forces in the Black Sea, but was largely entrusted by the government with the duty of transporting troops and stores to the seat of war. At that time it was a considerable purchaser of British tonnage. In 1857 it had the French mail contract to Algiers, as well as to the Danube and Black Sea ports, whilst in the same year a new mail contract for a service between Bordeaux and Brazil and the river Plate was granted to it. By this time it had, either afloat or under construction, a fleet of no less than fifty-four steamships of 80,875 tons. In 1861 further employment was found for its vessels in the conveyance of the mail to India and China. By the year 1875 its fleet embraced 175,000 tons of shipping, and also employed a large number of chartered sailing vessels. It was at that time the largest steam shipping company in the world. It had already ceased to employ British shipbuilders and now constructed its own tonnage in its own yards. The extension of its services to Japan followed, and eventually it put forth branches which served Madagascar, Mauritius and Zanzibar, as well as Australian ports and the French colony of New Caledonia. Some of the steamers employed in the mail services to the Far East and South are of a very fine character. In 1909 its fleet traversed 1,019,046 marine leagues and carried 197,320 passengers and over a million tons of cargo.

Morgan Combination.—Under the head of the *American Line* it has been shown how a group of American capitalists acquired the Red Star, Inman and American lines, thus forming a body of shipping which embraced in the year 1901 about 167,000 tons of shipping tonnage, partly under the British and partly under the Belgian and American flags. Another company which drew its capital chiefly from the United States, though its vessels fly the red ensign, is the Atlantic Transport Company, registered under the British Limited Liability Acts in 1889. Its main service is between London and New York, and it is carried on by large and modern twin-screw steamships, several of which have been constructed by Messrs Harland & Wolff of Belfast. These vessels range up to about 14,000 tons gross register, and though they carry large quantities of cargo and of cattle on the eastward voyage, also accommodate a number of passengers in their saloons. Through the connexion of this undertaking with Messrs Harland & Wolff as builders of their vessels, those American capitalists who were interested in the extension of United States interests on the North Atlantic and who purchased the share capital of the Leyland Line were brought into connexion with Lord Pirrie, the managing director of this ship-building firm, and through him approach was made to the managers of the White Star Line in the year 1901. An offer for the purchase of this famous British line was put forward by the American syndicate, headed by Mr J. Pierpont Morgan. The managers of the White Star Company had not merely to consider what many experts believed to be a liberal offer. There was another factor in the situation present to their mind. The New York syndicate, besides having the control of the vessels of the American lines on the Atlantic, had, it was said, secured the management of the trunk lines of railway between the great producing districts of the Western states of America and the eastern seaboard. They were thus in a position to give to shippers from the United States the convenience of transit by a through bill of lading to embrace both the railway journey and the ocean voyage, and there was ground for the belief that if competition were allowed to ensue the British steamship companies—which from the nature of things could receive no corresponding support from the railways of the United Kingdom—might suffer very severely. The White Star Line accordingly threw in its lot with the American and Atlantic Transport Companies, and with the White Star Line went the Dominion Company—a line whose fine passenger vessels were constructed by Messrs Harland & Wolff, and whose management is largely influenced by the partners in that firm. The Dominion Line has services from Liverpool to Boston, Portland (Maine), and St Lawrence ports. The Norddeutscher Lloyd and the Hamburg-American companies were approached by Mr Morgan with a view to their entering into the scheme; but though a working agreement was arranged, the German lines decided to preserve their separate existence. The Morgan combination was eventually incorporated at the end of September 1902 in New Jersey as "The International Mercantile Marine Company," with a capital of $120,000,000; and an agreement was come to with the British government, by which the British character of the British ships in it would be preserved. The combine controls about a million tons of steamships.

Navigazione Generale Italiana.—The union of the Florio and Rubattino lines in the year 1882 was the origin of this company. The Rubattino Line finally made Genoa its headquarters, while the Florio Line centred its business at Palermo, and had itself been largely strengthened by the absorption of the Trinacria Company of its own port. The coasting trade of Italy and Sicily, with services to various ports of the Mediterranean and Black Seas, occupies the great part of the company's fleet. But it also runs monthly lines from Genoa through the Suez Canal to Red Sea ports, and so to India and Hong-Kong. Towards the western ocean it has a service maintained in conjunction with that of another Italian company, La Veloce, to Brazil and the River Plate, whereby weekly departures are made from Genoa. In February 1901 a new line was opened by the sailing of the Italian Generale Company's steamship "Liguria" —a new Italian-built vessel of upwards of 5000 tons register—for New York. The object of this line, which is maintained by steamers of the Generale Company, aided by a similar number from the fleet of La Veloce, sailing once a week from Genoa via Naples, is to attempt to retain in Italian hands some of the large traffic which is carried on from these ports in the steamers of the Norddeutscher Lloyd, the Hamburg-American Line, the Cunard and White Star lines.

New Zealand Shipping Company.—This company was established in 1872 for the purpose of maintaining a passenger and cargo service between London and New Zealand. This was before the days when steam vessels could be used with commercial success in the long sea trade. At first it depended on chartered vessels, but gradually it acquired a fleet of fast clipper iron sailing-ships which reduced the voyage to 90 days. These vessels took out a large number of government emigrants between 1874 and 1882. In 1881 one of these ships inaugurated the frozen meat trade from New Zealand, thus opening up a business which has since grown to colossal proportions. The trade increased so rapidly that it was found impossible to conduct it by means of sailing ships, and in January 1883 the company despatched from London the chartered steamship "British King," of 3559 tons. This vessel accomplished the voyage in 50 days, but it was found necessary to diminish the passage to 45 days out and 42 home. Five steamers were therefore built to fulfil the requirements of the trade. The first of these, the "Tongariro," of 4163 tons, left England in October 1883. The company about this time received the contract of the New Zealand government for a monthly mail service, with a guaranteed time of 45 days. The managers gradually eliminated all the sailing vessels from the fleet, and more recently replaced the original single-screw mail steamers with large modern twin-screws. In addition to passenger vessels the company owns several cargo boats, some of which are among the largest afloat. In the "Otaki" triple-screw vessel, added to the fleet in 1907, the company initiated a combination of reciprocating engines for using the high-pressure steam and turbines to make use of it subsequently. The company's ships sail from London, calling at Plymouth, Teneriffe, Cape Town, Hobart, on the way out, and sometimes at Montevideo or Rio and Teneriffe on the return voyage. Communication with the different ports of New Zealand, as well as to Australian ports, is carried out by the vessels of the Union Steamship Company of New Zealand.

Norddeutscher Lloyd.—To the enterprise of certain citizens in the city of Bremen this large business owes its existence. The originator was Herr H. H. Meier, who brought into line the various shipping interests of Bremen, and induced them to amalgamate into one company. The associations thus brought together were the Weser Haute Steamship Company, the Unter Weser and Ober Weser Steam Tug Companies and the Ober Weser Universal Shipping Insurance Association. The statutes of the new company were approved by the senate of Bremen on the 18th of February 1857. The original capital was 4,000,000 thalers, but soon after the formation of the new company great depression set in, owing to the commercial crisis in North America. More than 2500 shareholders in the Lloyd forfeited their shares, but the directors were not dismayed, and had the loyal support of their fellow citizens. Four big ocean steamers were constructed for the American line and three for the English, and large docks for repairs were established at Bremerhaven. The first voyage was made in June 1858, when the "Bremen" started for New York, carrying many steerage passengers, but only one in the saloon. The second ship, the "Hudson," was shortly afterwards burned while lying in harbour. At the end of the first year both lines showed a loss. At the end of the second year matters improved, the English cattle trade especially showing great progress. But the company still commanded little confidence, for the Darmstadt Bank parted with 1,000,000 thalers' worth of shares at a loss of 75%. These the directors themselves took over. But the American Civil War now came, to deal another severe blow at the Lloyd, just when its prospects were growing brighter, and till 1864 no dividend greater than 2½% was paid to the shareholders. After the termination of the war the trade with the United States grew enormously, and the English traffic also revived in a most unexpected way. One result was the foundation of rival lines, which, however, were unable to maintain effective competition, and succumbed. In 1868 a new line was opened. Bremen's staple of commerce is tobacco, and the directors determined to bring their port into direct communication with the tobacco-producing areas in the States; so in that year they inaugurated their line to Baltimore. In the following year a line was started to New Orleans, another great centre of the tobacco and cotton trade. It was necessary to construct three special liners for that service, as the ordinary ships could not pass the bar of the Mississippi. In 1869 a line to Central America and the West Indies was set on foot, and new steamers were ordered to run on it. With the outbreak of the war of 1870 the company naturally had anxious times, as the French fleet blockaded the German coasts; but its vessels often ran the blockade with success. Soon after the war the West Indian service, proving unprofitable, was given up. In 1875 a new line of steamers to Brazil and Argentina was started. This was separated into two distinct services in 1878. In 1880 the approach of the great struggle for supremacy on the Atlantic made itself felt, and the company began to prepare for the contest, and ordered the construction of the "Elbe," the first of its express line of steamers. She commenced running in 1881, and was quickly followed by others. Between 1881 and 1888 an entirely new fleet was placed on the New York line. In 1886 the Australian and East Asian Lines were founded in accordance with a contract with the imperial government. This included a monthly service to China, with a branch service to Japan, and a monthly service to Australia, with a branch line to the Samoan and Tonga Islands. From that time onwards the story of the Norddeutscher Lloyd has been one of increased prosperity. The company's fleet includes four large and fast steamships of about 23 to 23½ knots speed for its weekly express service to New York, whilst it has also large vessels—one, the "George Washington," being of 27,000 tons—for its intermediate service to the same port, built by the Vulcan Company at Stettin. The company runs many lines from its headquarters at Bremen; among them are those to New York—a line of express steamers and a line of ordinary mail steamers, all calling at Southampton or Cherbourg; to Baltimore direct; to Galveston direct—there are no first-class passengers by this line; to Brazil; to the River Plate, calling at principal ports on the way. There are also lines of imperial mail steamers between Bremen and Hamburg and eastern Asia, and Bremen and Australia, and a freight line to east Asia, which runs in connexion with the Hamburg-American Line. In pursuance of the German policy of securing the feeders to maintain traffic, the Norddeutscher Lloyd purchased the ships and business of the Kinsing Line and of the Scottish Oriental Company, when it began seriously to develop its Eastern trade. Feeling in common with all large steamship companies the difficulty of providing efficient personnel for its constantly expanding fleet, and believing in the necessity for seamen of experience in masted ships, the Lloyd has provided itself with a sea-going training-ship. Such success attended this experiment that a second vessel has been added and the idea has since commended itself to certain British steamship companies.

Ocean Steamship Company.—The Ocean Steamship Company is the successor of older steamship enterprises, mainly under the same management and ownership. These began in 1852 with the coasting trade, and extended in following years to French ports, and in 1855 to the West Indies. The last-named line attained some moderate importance, comprising seven vessels; it was sold in 1863, and eventually became the West India & Pacific Steamship Company, which in its turn was absorbed by the Leyland Line in 1900. The managers thereupon, seeking other trades, decided on attempting that to China, and the company under its present title was registered as unlimited in 1875. Up to this date low-pressure jet-condensing engines were alone used, burning perhaps 5 to 5½ ℔ of coal per indicated horse-power per hour. This rate of consumption would have been fatal to the scheme, since vessels could not have carried any cargo in addition to the coal necessary for so long a voyage as that via the Cape, the Suez Canal not being opened till 1870. A small vessel, the "Cleator," of which the exact speed and consumption with the old type of engine was well known, was therefore experimentally fitted with new machinery of the compound high-pressure (70 ℔), surface-condensing type. The result of the experiment was that her consumption was reduced to about 3 or 3½ ℔ per i.h.p. per hour, and this warranted the construction of the "Agamemnon," "Ajax" and "Achilles," all 309 ft. long, 38 ft. 6 in. broad, 28 ft. 6 in. deep, fully rigged as barques, with screws outside their rudders. These rigs were subsequently altered to that of barquentines, but the relative positions of the screws and rudders were retained till they were disposed of in 1899. In these vessels the consumption was further reduced to about 2¼ ℔, which allowed margin for a reasonable cargo. The "Agamemnon" sailed from Liverpool in 1866; the itinerary being Mauritius, Penang, Singapore, Hong-Kong and Shanghai, and, with similar calls, back to London. The cargoes in those days were mainly manufactured goods outwards and tea homewards. The average speed was perhaps 9¾ knots, and the consumption about 21½ tons of Welsh coal per day. These and succeeding steamers were at that date the only vessels carrying high-pressure steam on long voyages, and they traded regularly round the Cape, being the only line that did so. When the Suez Canal was opened in 1870 they changed the route. The trade from the United Kingdom to China has since steadily grown, and increasingly large cargoes are also procurable homewards from the Far East, in spite of the successful competition of Indian and Ceylon teas. In 1891 a service was begun from Amsterdam and Liverpool to Java, and this is maintained about once a fortnight, finding employment for about ten of the smaller ships. The vessels in this trade, which is principally between Holland and her eastern possessions, fly the Dutch flag. A limited number of passengers were formerly carried between England and the East, but these ships now take cargo only to and from Europe, though Mahommedan pilgrims are conveyed in considerable numbers to and from Jeddah, the port for Mecca. The ships generally commence loading at Glasgow, and occasionally at other West Coast ports. They usually carry the greater part of the cargo from Liverpool, the most important element being fine goods (manufactured cottons, &c.) from Lancashire and Yorkshire. Abroad the regular service has been extended to the principal Japan ports—Nagasaki, Kobé and Yokohama, and, as opportunity arises, additional ports of call in China and Korea have been added to its itinerary. The following local services have their headquarters at Singapore: (1) Singapore to West Australian ports, including Fremantle. These steamers carry passengers, and bring large quantities of wool and pearl shell from Australia to Singapore for transshipment to the main line steamers bound for London. (2) Singapore to Deli (Sumatra). Three small steamers bring tobacco from Deli for transshipment to Europe. (3) Singapore and Penang to China. The great emigration of Chinese coolies to the British colony of the Straits Settlements keep several steamers regularly employed. The company is colloquially known in the shipping world as the "Blue Funnel" Line, and is also often referred to by the name of Mr Alfred Holt, who has been closely identified with it throughout its history. In 1902 the Ocean Company absorbed its younger rival, the China Mutual Steam Navigation Company, with a fleet of thirteen vessels of 106,870 tons, and shortly afterwards re-registered itself under the Limited Liability Acts. The company's most recent development is in its connexion with Australia. For its direct service thither several 10,000-ton ships fitted with refrigerating apparatus and accommodation for some 300 passengers each are provided.

Orient Line.—The Orient Line of steamers between London and Australia took up the work of the Orient Line of clipper packets, which in the days of sailing-ships used to ply between London and Adelaide. In April 1877 it was announced that "the Orient Line would sail the under-mentioned steamships of the Pacific Steam Navigation Company to Australia." That connexion between the two organizations was continued and strengthened till in 1901 the name of Orient Line was changed to that of Orient-Pacific. In June of 1877 the "Lusitania" was despatched from London to Adelaide, Melbourne and Sydney, via the Cape of Good Hope. Other sailings followed at about two-monthly intervals. In the following year the Orient-Pacific Line came into existence. It was formed by the joint efforts of Messrs Anderson, Anderson & Co. and F. Green & Co., who are the managers of the line. When the service was begun it was intended to be run monthly, but the increase of traffic soon demonstrated that fortnightly sailings would be successful. This extension was determined on in 1880, the year following that in which the "Orient," the first ship specially built for the company's trade, commenced work. Since 1888 the Orient Company has carried the mails to Australia by contract with the English post office, once a fortnight. These despatches, alternating with those of the P. & O., give Australia a weekly mail. Several twin-screw steamers have been built for this service by both the Orient and the Pacific Companies. The latter company subsequently retired from the partnership, the Royal Mail Company taking its place and purchasing the vessels which it employed. In 1910, however, a new mail contract came into operation, and this was undertaken by the Orient Company alone. The Royal Mail withdrawing its ships, the Orient Company replaced them with a new fleet of 12,000-ton steamers, of which the first five are twin-screws and the sixth is to have three propellers driven by a combination of reciprocating and turbine engines. It was the Orient liner "Ophir" which took the place of a royal yacht for the imperial tour of the Prince and Princess of Wales in 1901. The steamers of the Orient Line call regularly at Plymouth, Gibraltar, Marseilles, Naples, Port Said, Suez, Colombo, Fremantle, Adelaide, Melbourne and Sydney.

Pacific Steam Navigation Company.—This was the pioneer of the steam-trade along the western coast of South America; subsequently its operations were extended to Europe, and finally, in conjunction with the Orient Steam Navigation Company, it established the Orient Line to Australia, from which it withdrew in 1906. It obtained a charter early in 1840, and soon sent out from England two steam vessels, the "Chili" and "Peru." These were paddle-boats of 710 tons and 198 ft. in length. They ran along the coast from Valparaiso to Panama. The early struggles of this company are noteworthy as showing how difficulties, apparently insuperable, may be overcome, and even turned to essential advantage. The great obstacle to the success of these steamers was the difficulty of obtaining supplies of fuel, and in the first five years of its existence no less than £72,000 was lost, the whole capital of the company being but £94,000. But the difficulties were overcome, and all that remained in the mind of the managers was a strong feeling of the importance of economy in coal consumption. Accordingly, in conjunction with the Fairfield firm of Randolph, Elder & Co., they turned their attention in this direction, and were sending out vessels fitted with compound engines some ten or a dozen years before the Atlantic companies adopted them. In 1867, under pressure from the Chilean government, the company sought and obtained powers to extend its operations, and in the same year the "Pacific," of 1630 tons, was constructed. She left Valparaiso for Liverpool in May 1868, the first of the new mail line. In 1870 the voyage was extended, Callao, 11,000 miles from Liverpool, being made the terminal port, and the sailings were increased from one to three a month. In 1873 a weekly service between Liverpool and Callao was instituted, and by 1874 there was a fleet of fifty-four steamers, with an aggregate of 120,000 tons, in commission. Owing, however, to a great decrease in the South American trade the service was reduced to a fortnightly one. The opening of the Transandine railway was expected to have a great effect on the fortunes of shipping companies in South American waters and consolidation of interests seemed desirable. In 1910 the whole of the company's ordinary capital was purchased by the Royal Mail Company, and the line was thus absorbed. In January 1893 the company inaugurated a monthly cargo service to the Brazils, River Plate and the West Coast. This service has been extended to Glasgow. Many ports are served. The principal are La Pallice, La Rochelle, Corunna, Carril, Vigo, Lisbon, St Vincent, Pernambuco, Bahia, Rio de Janeiro, Montevideo, Buenos Aires, Punta Arenas, and the ports of the western coast of South America, Valparaiso and Callao.

Peninsular & Oriental.—The story of the P. & O. Company may be divided into two eras—the first reaching from its foundation to the opening of the Suez Canal; the second from that date to the present day. During almost the whole of its career the company has acted as the agent of the British government in the conveyance of its mails, first to Mediterranean ports, and afterwards to Egypt, India and the Far East. From time to time the government has made efforts to procure some other means for transmitting its mails, but on every occasion it has found it advisable to return to the P. & O. In 1835 Messrs Willcox & Anderson, a firm of London merchants, began to run steamers to the principal ports of the Peninsula. Their vessels observed greater regularity than the sailing-ships then employed to carry the mails, and the first mail contract was entered into on the 22nd of August 1837. This was awarded to them after another company, which was unable to fulfil its obligations, had been engaged for the work. Messrs Willcox & Anderson had shortly before, in concert with Captain Bourne, R.N., founded the Peninsular Company. This contract arranged for a monthly service between Falmouth and Vigo, Oporto, Lisbon and Gibraltar. About two years later another step was taken. Hitherto the mails to Egypt and India had been conveyed by the Peninsular Company to Gibraltar, by an admiralty packet from Gibraltar to Malta, by another admiralty vessel from Malta to Alexandria, and from Egypt to Bombay by one of the East India Company's steamers. It was resolved to substitute for this unsatisfactory mode of conveyance a direct system of carriage by one line of steamers from London to Alexandria. The Peninsular Company again secured the contract, which was put up to public competition, and built two steamers of 1600 tons for the purpose this being a large tonnage for those days. The annual subsidy was fixed at £34,000, by which the government saved £10,000 of the amount formerly expended on their own inefficient means of transport. The company then, by a charter of incorporation, dated December 1840, assumed the name by which it has ever since been known—The Peninsular & Oriental Company. The charter was granted only on the onerous condition that steam communication with India should be established within two years. The first steamer, the "Hindostan," was despatched to India via the Cape of Good Hope on the 26th of September 1842. She was one of a small fleet destined to ply between Calcutta, Madras, Ceylon, Aden and Suez. It was an adventurous undertaking, for the East India Company promised no definite subsidy, only a small premium on a certain number of voyages.

The obvious advantages of a direct conveyance of mails between Suez and Bombay by a regular sufficient service were becoming evident, and the P. & O. Company offered to effect this at a great saving on the existing system; but, for some reason or other, the East India Company showed the greatest reluctance to allow the control of this route to pass out of their hands, in which, in fact, it remained until 1854. Fortunately for the P. & O. Company the government decided to establish regular monthly steam communication between England and Ceylon, Madras and Calcutta, and also from Ceylon, eastward to Singapore and Hong-Kong. Only the P. & O. could at that time have comtemplated undertaking such a service. In 1844 the contract was signed, and by it the company was to receive a subvention of £160,000. The Indian portion of the service opened on the 1st of January 1845, and during that year the extension to China was effected, and nine new steamers were put on the stocks. The organization of the overland route was due to the P. & O. Company, which brought it into regular working in order to convey its passengers from Alexandria to Suez. It was a picturesque but uncomfortable passage by canal-boat and steamer to Cairo, then by a two-wheeled omnibus for ninety miles across the desert to Suez. Even the coal for the boats at Suez had to be transported in this fashion, which was cheaper than sending it by sailing vessel round the Cape. The construction of a railway across the isthmus in 1859 greatly simplified the transit. It may be noted that the company had to establish coaling stations between Suez and the Far East, and also dépôts of provisions, a business of no less magnitude than that of the steam service itself. In 1852 the first mail service to Australia was undertaken by the company, and the same contract included an arrangement for a fortnightly service to India and China, though a service running once every two months via Singapore and Sydney was thought sufficient for the requirements of Australia. The year 1854 saw the abolition of the East India Company's service to Bombay, the P. & O. taking its place. This arrangement saved the country £80,000 per annum. The Crimean War made large demands on the company's resources for the conveyance of troops, and the Australian service was for a time interrupted. By 1859 the company was in possession of all the lines of steam communication between England and the East. In 1864 the service to Australia was increased to one sailing a month, and in 1868 the Bombay mail left weekly. About the same time the fourth India and China contract was entered into, and at the end of 1869 the opening of the Suez Canal led to a serious crisis in the company's affairs; and also, after these difficulties had been surmounted, to a complete revolution in its methods. The opening of the canal led to a prolonged controversy with the post-office, which, with true official perversity, would not allow the company to use the canal for the conveyance of its mails. A serious falling-off of the company's revenue was the result, as the competition of the canal steamers was killing its trade. At length in 1874 a new arrangement was made by which the mails were to be carried through the canal, the subsidy granted to the company being at the same time reduced. Under these conditions, however, it was now able to construct vessels capable of competing successfully with its rivals. A prolonged dispute between Victoria and New South Wales for a long time prevented the Australian service from being as efficient as it might have been. Sydney insisted on the Pacific route being adopted. In consequence of this controversy the Australian headquarters of the company were for some time fixed at Melbourne, and it was not till 1888 that a general contract was entered into with the postmaster-general, acting at last for all the Australian colonies as well as for the Imperial government. This stipulated for an accelerated service—the India, China and Australian mails being all worked from Aden in connexion with the steamer which conveyed them from Brindisi. There was for long a service between Venice, Brindisi and Egypt, and a mail contract with the Italian government; but this came to an end in March 1900.

The company's first ship, the "William Fawcett," built in 1829, had a gross tonnage of 206 and 60 h.p. Down to 1851 the vessels of the fleet were all constructed with paddles; after that date the screw took their place, though for the Marseilles to Malta express service certain famous fast paddle-steamers were subsequently constructed. A later interesting development was the abandonment of Brindisi as a port of call for the ocean mail steamers, which reverted to Marseilles, whence they run across to Port Said direct. The mails leaving London every Friday night are despatched from Brindisi in specially designed twin-screw vessels, which land them at Port Said little more than 96 hours after their despatch from London. On this service the "Osiris" and "Isis" are employed, and they have the distinction of being the only vessels in the mercantile marine which cross the seas with mails and passengers only. The company is under contract with the British government for the conveyance of mails to India, China and Australia. Its services are as follows—India: Brindisi to Bombay, weekly. China; Brindisi to Shanghai, fortnightly. Australia: Brindisi to

Sydney, fortnightly. Apart from the mail services, the company runs independent lines to Malta, Colombo and Calcutta; also between Bombay, Colombo, Singapore, Hong-Kong and Shanghai; and between Hong-Kong, Nagasaki, Hiogo and Yokohama. There is likewise a direct fortnightly service of through steamers to China and Japan at special rates. The mails are despatched weekly to Bombay, going one week by direct mail steamer and the next by the fortnightly Australian liner as far as Aden. A fast twin-screw vessel—the "Salsette"—built after the idea of the "Isis" but of thrice her tonnage—takes the Bombay mails from Aden on the weeks when there is no steamer. For the Indian and Australian mail services a new type of steamer known as the "M" class has been provided. There are already no less than ten such vessels, all twin-screws of similar design, commencing with the "Moldavia," built 1903, of 9500 tons and 14,000 i.h.p. and running up to 12,500 tons and 15,000 i.h.p. in the "Maloja" and "Medina." In 1910 a new service was acquired, the Blue Anchor fleet of Mr Wilhelm Lund being purchased. This gave the company an entry into the South African trade, the Blue Anchor steamers calling at Cape Town and Durban on their way to Australia, and new and larger vessels are being provided for this branch also of the company's activities.

Shaw, Savill & Albion Company.—The amalgamation of the business of Messrs Shaw, Savill & Co. of London and of the Albion Shipping Company of Glasgow brought this company into its present form at the close of the year 1882. At that time the amalgamating firms owned a large fleet of sailing-ships, and traded chiefly between England and New Zealand. Soon, after the amalgamation the company began to acquire steamships, which gradually supplanted their sailing vessels. The Shaw, Savill & Albion Company were among the first in the frozen meat trade, and their vessels are fitted to carry large numbers of carcases. With this company the White Star Line of Liverpool became associated in the year 1884, and five of their ships now run in the fleet of the Shaw, Savill & Albion Company. In June 1910 an offer was made by Sir John Ellerman to take over the fleet, which at that time consisted of six twin-screw and five single-screw steamships with a total of 51,300 tons gross register, a twelfth vessel being under construction. The route to New Zealand is by the Cape of Good Hope on the outward voyage, returning by Cape Horn, thus going completely round the globe every voyage. After leaving London the steamers call at Plymouth, Teneriffe, Cape Town, Hobart and Wellington; returning from New Zealand, the ports touched are Rio (sometimes Montevideo), Teneriffe, Plymouth, London. The "Arawa," which came out in 1884, made the outward voyage in 38 days, and the run home in 35 days 4 hours steaming time; she thus made the circuit of the world in 73 days 4 hours net time.

Union Steamship Company (see *Castle Line*).—This company first came into existence in 1853 under the name of the Union Steam Collier Company, with a capital of £60,000. At its commencement it possessed a fleet of five small steamers with an aggregate of only 2337 tons. But by the time these vessels were built the Crimean War was being actively carried on, and it was thought advisable to employ them for other purposes than those for which they were originally intended. They ran for a time between Southampton, Constantinople and Smyrna; but the transport service proved more remunerative, and they were used for the conveyance of troops. At the close of the war the company was registered under the Limited Liability Act by its present name. It was then determined to run the vessels between Southampton and Brazil with cargo, but this did not prove profitable, and in 1857 a notable change took place in the status of the company, for in that year it took its place among the great ocean mail companies of England. In that year a contract was completed with the government for a monthly mail service for five years to the Cape of Good Hope at an annual subsidy of £30,000. The "Dane" was the first steamer to leave Southampton with the mails on the 15th of September. In 1858 the subsidy was increased in order that the company's ships might call at St Helena and Ascension for mails on the homeward voyage. When the first contract expired the company secured another for five years. A service between the Cape and Natal, under a temporary arrangement, was inaugurated in 1862, and a seven years' mail service contract with the Natal government was concluded in 1865. In 1873 the House of Commons refused to ratify a contract which the government had entered into with the company for an extended mail service; the company, however, carried out its intention to extend its service to Zanzibar. But in October 1876 a new mail contract with the Cape of Good Hope government was entered into for a fortnightly service between Plymouth and Table Bay, the length of voyage not to exceed twenty-six days. During the Zulu War this company rendered considerable services to Great Britain. In 1878 three ships were employed, and after Isandula they conveyed reinforcements, the "Pretoria" being the only mail steamer to carry an entire regiment, the 91st Highlanders. It was on this company's s.s. "Danube" that the prince imperial sailed, whilst the old s.s. "German" took out the Empress Eugénie when she went to visit the scene of his death. The direct service with the Cape, Natal and Zanzibar was in 1881 discontinued, and in February of that year operations were extended to the Continent, a service from Hamburg was commenced, running every twenty-eight days, which for a time proved highly successful. A branch service to Antwerp, begun in 1882, was discontinued for a time, but subsequently resumed. At the time of the Panjdeh scare in 1885, when hostilities were threatening with Russia, two of this company's steamships, the "Moor" and the "Mexican" were selected to act as armed cruisers for the defence of South Africa. The former was the only merchant vessel on which the pennant was actually hoisted. In 1889 the company's continental traffic increased so that it not only resumed the despatch of through steamers from Hamburg, but made calls at Rotterdam. This service afterwards became fortnightly, calls being made at Rotterdam, Antwerp and Hamburg. New contracts with the colonial governments were made in 1888, and in the same year Southampton took the place of Plymouth as the outward mail port, while in 1889 the homeward mails were landed at Southampton in place of Plymouth. In 1889, by the construction of the "Scot," the company acquired a much larger vessel than any they had hitherto employed; in 1895 Messrs Harland & Wolff successfully accomplished the task of lengthening this ship by cutting her in two amidships and adding 54 ft. to her length and 1000 tons to her tonnage. She subsequently was altered to adapt her for public yachting purposes and transferred to the German flag under the name of "Oceana." In 1893 the company entered upon its new policy of building a large number of practically sister ships for its intermediate trade. All were built by Messrs Harland & Wolff, and fitted with twin-screws. The series included ten vessels, commencing with the "Gaul" of 4745 tons, and ending with the "Galician" of 6757 tons launched in 1900. Meanwhile from the same yard the mail steamers "Norman," "Briton" and "Saxon" were added to the fleet. The last-named, which came out in 1899, is a vessel of 12,385 tons, with a length of 570 ft. By a resolution passed at a meeting of shareholders held on the 13th of February 1900, this company was amalgamated with the Castle Line (see below). At its absorption its fleet consisted of twenty-three vessels, of which nine were over 6000 tons.

Union-Castle Line.—This company was formed by the amalgamation of the Union and Castle lines. Previously, though practically all the vessels made their final departure from Southampton, the Union Line only made its headquarters at that port, the Castle liners coming round from London. After amalgamation, the mail steamers—to which cargo is not of so much importance—did not come to the Thames at all, the increase in their size and the neglect of the improvement of the river and of the docks by the authorities making it undesirable that they should do so. The cargo (intermediate) liners, on the other hand, all load in London, and many of them, before their final departure from the Thames, visit Hamburg, Antwerp and Rotterdam, for the purpose of picking up cargo. On these North Sea trips passengers are carried, and facilities are given for their accommodation on board during the calls at the various ports. The new company carries out the contracts of its two constituents and thus despatches every Saturday a mail steamer from Southampton via Madeira to the Cape and Natal. An hour or so before the sailing of the mail boat an intermediate steamer departs from the same port. Her places of call are Teneriffe or Las Palmas for certain, and possibly also Ascension and St Helena. These vessels serve the east coast ports of Algoa Bay and East London as well as Natal. Some of them also go to Delagoa Bay, to Beira on the mainland, and to the island of Mauritius. In 1910 a further extension was made, a monthly service being instituted to East Africa through the Canal. Besides the two weekly vessels, however, there are despatches of extra mid-weekly intermediate steamers, and these extra sailings have recently tended to become more frequent. The company's attention has for some time been directed to the trade between the United States and South Africa, and within two years after amalgamation eight new steamships were constructed with a view to the development of the trade between Cape ports and New York. Nor did the union of the two companies stop the improvement of the general fleet. The 10,000-ton twin-screw mail steamers "Kinfauns Castle" and "Kildonan Castle" were delivered to the Castle Company from the Fairfield yard prior to the amalgamation. Messrs Harland & Wolff had the "Saxon," 2000 tons larger than these ships, well in hand at the time. But the "Walmer Castle," a larger and still later addition to the fleet, embodied as far as possible the practice which from experience commended itself to both the old companies. Subsequent additions to the mail fleet have been the sisters "Armadale Castle" and "Kenilworth Castle," followed in 1910 by the "Edinburgh Castle" and the "Balmoral Castle" of 13,300 tons each. Provision is now made for the carriage of the mails exclusively in twin-screw vessels. Meanwhile the intermediate fleet has received several vessels of large dimensions and of comfortable accommodation, though of speed inferior of course to the mail steamers. The company proved its capacity in the South African War, when it carried vast bodies of military and civilian passengers by its regular steamers at a time when many of its vessels were chartered by the government as troopers and storeships. In spite of the strain put on the resources of the company by the heavy work entailed by the South African War, both on the vessels employed in their regular service and on those especially taken up for government transport duty, it was found possible already to discard two of their older vessels.

White Star Line.—Though perhaps chiefly known in the New York trade, the White Star flag was first hoisted in the middle of last century over a fleet of clippers which sailed to Australia. In 1867 Mr Thomas Henry Ismay took it over, and two years later the great revolution in the constitution of the company took place. It was in 1869 that Mr Ismay formed the Oceanic Steam Navigation Company to run a line of steamers between Liverpool and New York. Immediately on its formation the company entered into arrangements with Messrs Harland & Wolff of Belfast for the construction of a fleet of high-class passenger ships, and it is worthy of notice that the terms upon which Messrs Harland & Wolff built the White Star ships were peculiar. No definite price was agreed upon, but the actual cost plus a percentage for builders' profit was charged. The first "Oceanic," pioneer steamship of the line, was launched on the 27th of August 1870, and sailed for New York on the 2nd of March 1871. Her advent opened a new era in Atlantic travel. She introduced the midship saloon, which extended the whole width of the ship, thus giving increased light and improved ventilation, and reducing to a minimum the sensation of the vessel's motion. The arrangement thus introduced is now almost universally adopted in the construction of ocean liners. The "Oceanic" was also narrower in proportion to her length than the vessels previously designed for the transatlantic mail service. In 1877 the "Britannic" reduced the passage to 7 days 10 hours and

[1] This table is based on that contained in a paper on "Shipping Subsidies," by B. W. Ginsburg, published in the *Journal of the Royal Statistical Society* (September 1901).

[2] The Leyland Line was formerly the Leyland Line and West India & Pacific Steam Navigation Company.

[3] In 1891 the old American Line had 3 steamers of 10,166 tons; the Inman Line 6 steamers of 41,276 tons; the International Lin 4 steamers of 12,112 tons; and the Red Star Line 9 steamers of 39,609 tons.

[4] Messrs Elder, Dempster & Co. now control the fleets of the African, British & African, and Imperial Direct Steamship companies.

[5] Formerly the Union Line and the Castle Line. In 1891 the Union Line had 23 steamers of 55,576 tons, and the Castle Line 1 steamers of 57,934 tons.

[6] Formerly known as the Florio-Rubattino Line.

50 minutes, excelling by three hours the best previous Atlantic passage. After the year 1888 the company ceased to build single-screw steamers, all later vessels having been constructed on the twin-screw system, of which the superiority had been clearly demonstrated. About this time also the owners of the line became responsible for an important advance in steamship construction which was afterwards imitated by merchant ships of all the great maritime powers. The "Teutonic" and "Majestic," introduced in 1889 and 1890, were the first merchant ships constructed with a view to their use as possible auxiliaries to the Royal Navy. The former was present, armed with eight quick-firing guns, at the naval inspection by the German emperor in 1889. With the launch of the second "Oceanic" in January 1899 the company's record was still further enhanced. The White Star Line was from 1877 regularly employed under contract with the British government to carry the American mails from Liverpool and Queenstown to New York. Besides this weekly mail and passenger service, a fleet of twin-screw cargo vessels maintained a subsidiary service between Liverpool and New York. These vessels were especially designed for the conveyance of cattle and horses. After 1883 several steamships of the line were employed in the Shaw, Savill & Albion service between London and New Zealand. Three of the company's ships ran in the line of the Occidental & Oriental Company between San Francisco and Yokohama and Hong-Kong. The company inaugurated a service to Australia from Liverpool in 1899. Five ships ran in it (calling at Cape Town) to Albany, Adelaide, Melbourne and Sydney. The ports visited by their vessels in New Zealand will be found detailed under Shaw, Savill & Albion Company. In 1902 the absorption of the White Star fleet and management in the Morgan shipping combine was arranged. Since that time several alterations have taken place. The mail steamers of the line left Liverpool for Southampton in June 1907 and now call at Cherbourg on their way to and from New York. Two services are still maintained between Liverpool and New York—one the old cargo service, and the other a weekly despatch of large passenger and cargo vessels. In addition to these there are two other Atlantic services from Liverpool—one to Boston and the other maintained in conjunction with the Dominion Line to Canadian ports. There is also a line of White Star steamers between New York and the Mediterranean. Several important vessels from other limbs of the combine have been brought under the White Star flag, whilst the company has also practically absorbed the old Aberdeen Line.

Wilson Line.—Thomas Wilson, Sons & Co. is at the present time the largest private ship-owning company in the world. This line traces its origin as far back as 1835. It was founded by Mr Thomas Wilson in conjunction with Messrs Hudson and Beckington, and on the retirement of the two last-named gentlemen it acquired its present title. Early in the 'forties the firm was running three steamships to Gothenburg, and was engaged largely in the iron trade, importing large quantities of Swedish and Russian iron, and running a regular line of sailing boats to Swedish ports. It also despatched a regular service to Dunkirk. Steamships gradually superseded the sailing vessels, and new steamers year by year were placed on the Scandinavian service. About this time the firm secured the mail contract between England and Sweden, which it still holds. After the Crimean War it started the St Petersburg, Stettin and Riga trade. During the Franco-German War the trade to Stettin had to be suspended; and as a set-off the service to Trieste was inaugurated, which has developed into an independent Adriatic and Sicilian service. The Norwegian trade was then improved by the despatch of steamships to Bergen, Stavanger and Trondhjem, and subsequently a service of large steamers began running to Constantinople and the Black Sea. After the opening of the Suez Canal the trade to India, which has since assumed such considerable proportions, was inaugurated. In 1875 the firm launched out into a more hardy enterprise, by commencing to run steamers to America. Its vessels in 1902 ran to New York regularly from Hull and the Tyne ports. The original Calcutta trade was discontinued when the New York line was started, but in 1883 a service was established between Hull and Bombay. In 1891 the firm became a private limited company and in 1894 took over the coasting trade between Hull and Newcastle. The company employs a number of large and swift ships in the Norwegian passenger traffic, which in the summer season now reaches very considerable proportions. It has frequent services of passenger and cargo vessels to the ports of northern Europe, carrying passengers in the season as far north as the North Cape. Of course the winter season necessitates considerable variation of summer services to Baltic ports. In 1903 the fleet of the old-established Hull firm of Messrs Bailey & Leetham was absorbed, and in 1908 that of the North-Eastern Railway Company. There are also steamers leaving Grimsby, Manchester and Liverpool regularly for Scandinavian and Baltic ports; weekly services to Ghent, Liverpool and Newcastle; and services to Mediterranean and Black Sea ports. Besides the New York line there are ocean services to Boston, to New Orleans and the river Plate. There is also a weekly service to and from London and Boston in conjunction with the Furness-Leyland Line.

Conclusion.—The scope of this article will not allow of any detailed reference to many of the important foreign lines which in a complete history should be mentioned. The Hansa Company of Bremen; the Chargeurs Réunis of Havre; the Holland-American Line, which has of recent years added to the fleet several fine twin-screw liners, built at the Belfast yard; the Compañia Transatlantica of Barcelona, which performed so great a feat in the transport of troops from Barcelona to Cuba in the latter days of Spain's dominion over that island; the Pacific Mail Company of the United States; and many others might be noticed. A whole article might be devoted to the work of the lines on the North American inland waters, while there are several other English companies which might well claim attention, both from the magnitude of their operations and the extent to which they have developed types of ships suitable for the peculiarities of the trades in which their vessels are engaged. The Clan Line, for example, has largely adopted the turret-decked ship, which is the design of Messrs W. Doxford & Co. of Sunderland. This type of ship is intended to carry large cargoes on a small registered tonnage and a light draught, without paying for it by a sacrifice of weatherly qualities. The same object is aimed at by the design of the trunk steamers built by Messrs Ropner of Stockton. The Isherwood system of construction and the cantilever type of cargo steamer are other devices for attaining the same object. Then there are the tank steamers constructed for the carriage of oil in bulk. Many of these ships are adapted not only for the carriage of oil, but also for its consumption in their furnaces in place of coal. We have already referred to some of the vessels fitted with refrigerating apparatus for the carriage of dead meat, and to the cargo steamers of the Atlantic companies, which are supplied with conveniences for carrying valuable racehorses and cattle. The experience of many years has enabled the owners of some of these lines to exhibit a wonderfully low record of loss, the percentage of deaths at sea to numbers carried being small beyond the dreams of, say, the 'seventies. A tenth of 1% over a somewhat extended period is not an unprecedented average.

The table shows something of the recent growths of companies, and at the same time records some of the amalgamations which have been so frequent. It should be explained that the table does not pretend to be exhaustive. The fleets embraced in it are not necessarily all those whose tonnage reaches above the lower limit shown. There are now a number of lines whose total exceeds 100,000 tons which are not shown in the list. Amongst them may be cited the Hamburg-Pacific Line, the German line to Australia, the Union Company of New Zealand—which contains many small vessels, the Forende Company of Copenhagen and the Anglo-American Oil Company. The table shows how whilst the principal lines are largely increasing their fleets, one or two companies are falling back in their gross amount of tonnage. The figures, moreover, are subject to certain reservations. The count was not necessarily taken by the various companies at the same period of each year. Some of the figures given may include numbers and tonnages of tugs and tenders, while others may exclude them. Again, some of the companies may have returned in their fleets the vessels which they had under construction, whilst others may not have counted them. But none of these considerations can much affect the general significance of the figures shown. The growth in the average size of individual ships is as marked as that of the aggregate tonnage of the companies.

AUTHORITIES.—The following books throw much light on the history of the leading steamship lines: *History of Merchant Shipping*, by W. S. Lindsay (London, Sampson Low & Co.); *La Navig. comm. au XIX. siècle* (Paris, 1901); A. J. Maginnis, *The Atlantic Ferry* (3rd ed., London, Whittaker & Co.); E. R. Jones, *The Shipping World Year-Book*; *Lloyd's Register of British and Foreign Shipping* (published annually). Also see a comprehensive article on this subject in the *Quarterly Review* for January 1900. Perhaps the fullest information is, as a rule, to be obtained from the handbooks issued by the companies themselves. (B. W. G.)

STEARIC ACID, *n*-Octodecylic acid $CH_3(CH_2)_{16}CO_2H$, an organic acid found as its glyceride stearin, mixed with palmitin and olein, in most tallows (hence its name, from Gr. στέαρ, tallow). The so-called "stearin" of candles is a mixture of stearic and palmitic acids (see CANDLE).

STEATOPYGIA (Gr. στέαρ, fat, πυγή rump), an unusual accumulation of fat in and around the buttocks. The deposit of fat is not confined to the gluteal regions, but extends to the outside and front of the thighs, forming a thick layer reaching sometimes to the knee. This curious development constitutes a racial characteristic of the Bushmen (*q.v.*). It is specially a feature of the women, but it occurs in a less degree in the males. It is also common among the Hottentots, and has been noted among the pygmies of Central Africa. In women it is regarded among them as a beauty: it begins in infancy and is fully developed on the first pregnancy. It is often accompanied by the peculiar formation known as "the Hottentot-apron," hypertrophy of the nymphae (Tablier). No satisfactory explanation of these malformations has been offered. Steatopygia would seem to have been a characteristic of a race which once extended from the Gulf of Aden to the Cape of Good Hope, of which stock Bushmen and pygmies are remnants. The discovery in the caves of the south of France of figures in ivory presenting a remarkable development of the thighs, and even the peculiar prolongation of the nymphae, has been used to support the theory that a steatopygous race once existed in Europe. What seems certain is that steatopygia in both sexes was fairly widespread among the early races of man. While the Bushmen and Hottentots afford the most noticeable examples of its development, it is by no means rare in other parts of Africa, and occurs even more frequently among Bastaards of the male sex than among Hottentot women.

STEDMAN, EDMUND CLARENCE (1833–1908), American poet and critic, was born at Hartford, Connecticut, on the 8th of October 1833. He studied two years at Yale; became a journalist in New York, especially on the staffs of the *Tribune* and *World*, which latter paper he served as field correspondent during the first years of the Civil War; and was a banker in Wall Street from 1869 to 1900. His first book, *Poems, Lyrical and Idyllic*, appeared in 1860, followed by successive volumes of similar character, and by collected editions of his verse in 1873, 1884 and 1897. His longer poems are *Alice of Monmouth: an Idyl of the Great War* (1864); *The Blameless Prince* (1869), an allegory of good deeds, supposed to have been remotely suggested by the life of Prince Albert; and an elaborate commemorative ode on Hawthorne, read before the Harvard Phi Beta Kappa Society in 1877. An idyllic atmosphere is the prevalent characteristic of his longer pieces, while the lyric tone is never absent from his songs, ballads and poems of reflection or fancy. As an editor he put forth a volume of *Cameos* from Landor (with T. B. Aldrich, 1874); a large *Library of* (selections from) *American Literature* (with Ellen M. Hutchinson, 11 vols., 1888–1890); a *Victorian Anthology* (1895); and an *American Anthology, 1787–1899* (1900); the two last-named volumes being ancillary to a detailed and comprehensive critical study in prose of the whole body of English poetry from 1837, and of American poetry of the 19th century. This study appeared in separate chapters in *Scribner's Monthly* now the *Century Magazine*, and was reissued, with enlargements, in the volumes entitled *Victorian Poets* (1875; continued to the Jubilee year in the edition of 1887) and *Poets of America* (1885), the two works forming the most symmetrical body of literary criticism yet published in the United States. Their value is increased by the treatise on *The Nature and Elements of Poetry* (Boston, 1892)—a work of great critical insight as well as technical knowledge. He died in New York on the 18th of January 1908.

See Laura Stedman and G. M. Gould, *The Life and Letters of Edmund Clarence Stedman* (2 vols., N. Y., 1910).

STEEL, FLORA ANNIE (1847–), English writer, was born on the 2nd of April 1847, the daughter of George Webster. In 1867 she married an Indian civilian, and for the next twenty-two years lived in India, chiefly in the Punjab, with which most of her books are connected; her interest in the education of women, as an inspectress of schools, gave her a special insight into native life and character. Some of her best work is contained in two collections of short stories: *From the Five Rivers* (1893) and *Tales from the Punjab* (1894); while her most ambitious effort was her novel, *On the face of the Waters* (1896), describing incidents of the Indian Mutiny. She also wrote a popular history of India. Later works are *In the Permanent Way* (1897), *Voices in the Night* (1900), *The Hosts of the Lord* (1900), *In the Guardianship of God* (1903), *A Sovereign Remedy* (1906).

STEEL CONSTRUCTION. The use of steel construction in the erection of large buildings is the natural consequence of the conditions imposed upon owners of property lying within sections of large cities, and the result of the introduction of new materials and devices. Apart from the aesthetic considerations to which has been due the construction of spires, towers, domes, high roofs, &c., the form and height of buildings have always been largely controlled by a practical consideration of their value for personal use or rental. The cost of buildings of the same class and finish is in direct proportion to their cubic contents, and each cubic foot constructed is commercially unprofitable which does not do its part in paying interest on the capital invested. Until the latter half of the 19th century, these considerations practically limited the height of buildings on city streets to five or six storeys. The manufacture of the wrought-iron "I" beam in 1855 made cheaper fire-proof construction possible, and, with the introduction of passenger lifts (see ELEVATORS; LIFTS or HOISTS) about ten years later, led to the erection of buildings to be used as hotels, flats, offices, factories, and for other commercial purposes, containing many more storeys than had formerly been found profitable. The practical limit of height was reached when the sectional area of the masonry of the piers of the exterior walls in the lower storey had to be made so great, in order to support safely the weight of the dead load of the walls and floors and the accidental load imposed upon the latter in use, as to affect seriously the value of the lower storeys on account of the loss of light and floor space. This limit was found to be about ten storeys. Various devices were successively made to reduce the size of the exterior piers. In 1881 the walls of a very large courtyard were constructed by building a braced cage of iron and filling the panels with masonry, a system of construction which had been used in the early part of the century for a tall shot-tower erected in the city of New York. Subsequently several buildings were erected in which the entire weight of the floors and roofs was carried by a system of metal columns placed against the inner surface of the exterior walls. The walls thus supported no load but their own weight, and were tied to the inner cage formed by the wall columns, interior columns, girders, and floors by anchors arranged to provide for the shrinkage of masonry in drying out which always occurs to a greater or less extent. By the use of this form of construction buildings were carried to the height of eighteen or nineteen storeys.

Iron or steel as a substitute for wood for constructive purposes was long thought to be fire-proof or fire-resisting because it is incombustible, and for this reason it has not only replaced wood in many features of building construction but is also used as a substitute for masonry. In time, however, it was realized that iron by itself is not fire-proof, but requires to be protected by means of fire-resisting coverings; but as soon as satisfactory forms of these were invented their development progressed hand in hand with that of iron and steel forms and combinations.

Buildings in steel are either of "skeleton" or "cage" construction. These terms may be defined as follows: In "skeleton" construction the columns and girders are built without proper or adequate inter-connexion and would not be able to carry the required weights without the support afforded by the walls; or, as in more recent construction, the walls are self-supporting and the other portions of the building are carried on by the skeleton steelwork. "Cage" construction consists of a complete and well-connected framework of iron or steel capable of carrying not only the floors but the walls, roof, and every other part of the building, and efficiently constructed with wind bracing to secure its independent safety under all conditions of loading and exposure, all loads being transmitted to the ground through columns at predetermined points. In America under this system the walls can be built independently from any level (see fig. 4), but in England the requirements of the building acts as to the thickness of walls prevents the general use of this form of construction.

Skeleton construction is defined by the Chicago building ordinance as follows:—

"The term 'skeleton construction' shall apply to all buildings wherein all external and internal loads and strains are transmitted from the top of the building to the foundations by a skeleton or framework of metal. In such metal framework the beams and girders shall be riveted to each other at their respective junction points. If pillars made of rolled iron or steel are used, their different parts shall be riveted to each other and the beams and girders resting upon them shall have riveted or bolted connexions to unite them with the pillar. If cast-iron pillars are used, each successive pillar shall be bolted to the one below it by at least four bolts not less than three-fourths of an inch in diameter, and the beams and girders shall be bolted to the pillars. At each line of floor- or roof-beams, lateral connexion between the ends of the beams and girders shall be made by passing wrought-iron or steel straps across or through the cast-iron column, in such a manner as to rigidly connect the beams and girders with each other on the direction of their length. These straps shall be made of wrought-iron or steel, and shall be riveted or bolted to the flanges or to the webs of the beams or girders.

"If buildings are made fire-proof entirely, and have skeleton construction so designed that their enclosing walls do not carry the weight of the floors or roof, then their walls shall be not less than twelve inches in thickness; and provided, also, that such walls shall be thoroughly anchored to the iron skeleton, and provided, also, that, whether the weight of such walls rests upon beams or pillars, such beams or pillars must be made strong enough in each storey to carry the weight of wall resting upon them without reliance upon the walls below them. All partitions must be of incombustible material."

Steel Cage Construction.

With the introduction of cheap structural steel, steel cage construction came rapidly into use. The dimensions of the exterior piers ceased to control the height of the building, which was limited alone by the possibility of securing adequate foundations, and by a consideration of the amount of floor space which could be devoted without too great loss to a system of passenger lifts of sufficient capacity to afford speedy access to all parts of the building. The advantages that led to the very rapid introduction of this system were not only the power of greatly reducing the size of the piers, but the enormous facility afforded for quick construction, the small amount of materials relatively used and the proportionately small load upon the foundations, and the fact that as the walls are supported at each storey directly from the cage, the masonry can be begun at any storey independently of the masonry below it. It is a disadvantage of the system that defects of proportion, material, or workmanship, which would be of less moment in an old-fashioned construction, may become an element of danger in building with the steel cage, while the possibility of securing a permanent protection of all parts of the cage from corrosion is a most serious consideration. The safety of the structure depends upon the preservation of the absolute integrity of the cage. It must not only be strong enough to sustain all possible vertical loads, but it must be sufficiently rigid to resist without deformation or weakening all lateral disturbing forces, the principal of which are the pressure of wind, the possible sway of moving crowds or moving machinery, and the vibration of the earth from the passage of loaded vans and trolleys, and slight earthquakes which at times visit almost all localities. In buildings wide in proportion to their height it is the ordinary practice to make the floors sufficiently rigid to transfer the lateral strains to the walls, and to brace the wall framings to resist them. In buildings of small width in proportion to their height this method of securing rigidity is generally found to be inadequate, and the frame is also braced at right angles to the outer walls to take up the strains directly. In each case all strains are carefully computed. The bracing is accomplished by the introduction at the angles of the columns and girders or beams of gusset plates or knee braces, or by diagonal straps or rods properly attached by rivet or pin connexions. All portions of the frame are united by hot rivets of mild steel or wrought iron, care being taken that the sum of the sectional areas of rivets affords in each case a sufficient amount of metal for the safe transfer of the stresses. The greatest care should be taken to see that all rivet holes are accurately punched, and if necessary that they are rhymed so that each rivet will have its full value.

For the proper and successful erection of the frame much depends upon an accurate alinement of the column bases. These should be properly tested as to position and level. The bases are either grouted with cement, or bolted to the foundations, but where cast column bases rest on masonry piers or footings any considerable grouting is not advisable. The only grouting that should be permitted in tall buildings would be in levelling up the tops of the concrete footings to receive the masonry courses, or in a very thin layer between the column pedestal and the masonry bed. The cap stones should always be brought to the most accurate bed possible, with grouting used as a thin cement and not as a backer. Accurate redressing of the cap stones after setting is much to be preferred.

All riveting and punching of the steel members is done at the shop, where also they receive the usual coat of oil or paint. This leaves the assembling and field riveting to be done on the ground, together with the adjustment of the lateral or wind-bracing, the placing of tie rods and the field painting.

Protection from Corrosion.

After erection the steelwork should receive one or two coats of paint; two coats are to be recommended, in which case they should be of different colours. Red lead is best for the priming coat and oxide paint for the finishing coat. In German specifications it is required that the steelwork should first receive a coat of boiled linseed oil, in order that the red lead coating should be more coherent with the steel.

Steelwork that has to come in contact with brickwork or concrete should not be painted, but should receive a wash of cement as the brickwork or concrete-work proceeds. The steelwork which is exposed to the weather should be painted about every three years, but when it is under cover an interval of five years may elapse.

To secure painting of permanent value a clean scaleless and rustless surface is first necessary. Steel plates and shapes, when delivered from the rolls which form them to the cooling beds, are largely covered with scales, which, adhering only partially to the surface, offer the intervening cracks or joints as vulnerable points for rust. After being rolled, structural steel is stored or handled out of doors for a varying period both at the mill and then again at the shop before the building is started. This period of open-air exposure allows the process of rust to start under the scales. If the rust so covered up has not begun to pit the iron the chances are that it will do no harm; but, if it is already well developed and of some thickness, it will have enough oxidizing agents in its pores to develop more oxide, and to swell up and crack the paint. The first requirement, therefore, for efficient painting is the careful removal of all mill-scale, rust, grease, or foreign substance, before even the priming coat is applied. It is agreed that the first step in the preservation of metal-work against deterioration or corrosion is the obtaining of absolute cleanness of metal before the application of paint or oil.

The following are the requirements of the New York building law in regard to the protection of iron or steelwork against corrosion, &c.:—

"All structural metal-work shall be cleaned of all scale, dirt and rust, and be thoroughly coated with one coat of paint. Cast-iron columns shall not be painted until after inspection by the Department of Buildings. Where surfaces in riveted work come in contact they shall be painted before assembling. After erection all work shall be painted with at least one additional coat. All iron or steel used under water shall be enclosed with concrete."

The Chicago ordinance makes no mention of paint or coating to prevent rust in metal framework. The London Building Acts do not set out any special requirements, but suggestions have been made at the Royal Institution of British Architects for the regulation of skeleton buildings and they are drawn up upon a more scientific basis than the bulk of the existing acts.

Columns.

In transferring the loads from the column bases to the bottom of the footings the greatest care must be taken in all systems of construction that the stresses throughout at no point exceed the safe limits of stress for the various materials used. Steel is generally used for columns in preference to cast iron, because it affords greater facility for securing satisfactory connexions, because its defects of quality or workmanship are more surely detected by careful test and inspection, and because, on account of its superior elasticity and ductility, its fibre is less liable to fracture from slight deformations. It is used in preference to wrought iron on account of its lesser cost.

Columns are generally built of riveted work of zedbars, channels, angles, plates, or lattice, of such form as will make the simplest and most easily constructed framing in the particular position in which the column is placed. The columns are sometimes run through two or more storeys and arranged to break joints at the different floors. In buildings to be used as offices, hotels, apartments, &c., it is usual in establishing the loads for the purpose of computation to assume that the columns carrying the roof and the upper storey will be called upon to sustain the full dead load due to material and the maximum computed variable load, but it is customary to reduce the variable loads at the rate of about 5% storey by storey towards the base, until a minimum of about 20% of the entire variable load is reached, for it is evidently impossible that the building can be loaded by a densely-packed moving crowd in all of its storeys simultaneously. In the case of factories and buildings used for storage purposes the maximum variable load which can be imposed for any serious length of time on each floor must be used without reduction in computing the loads of the lower column, and proper allowances must be made for vibrating loads. In the case of very tall exposed buildings of small depth, the vertical load on the columns due to wind pressure in the opposite side of the building must be computed and allowed for, and in case the lower columns are without lateral support their bending moment must be sufficient to resist the lateral pressure due to wind and eccentricity of loading. In computing the column sections a proper allowance must be made for any eccentricity of loading. It is usual to limit the height of sections of columns without lateral support to 30 diameters, and to limit the maximum fibre stress to 12,000 ℔ per sq. in. The sectional areas are computed by the use of the ordinary formulae for columns and struts.

The standard sections in use are numerous and varied, and from time to time a steel user has occasion to design a new steel shape because no existing section is suitable. The experiments given by Professor Burr indicate that a closed column is stronger than an open one, but practice does not always support theory, and many other questions besides mere form arise in connexion with the choice of a section; special considerations in the use of columns in buildings sometimes call for a form very different from the circular section, and such include the transfer of loads to the centre of the section, the maximum efficiency under loading, and the requirements for pipe space around or included in the column form. Lattice bars, fillers, brackets, &c., add just so much more weight without increasing the section, and must be allowed for; the method of riveting the sections together must also be taken into account.

Girders. For girders of small spans "I" beams or channels are generally used, but for greater spans girders are built of riveted work in the form of boxes with top and bottom plates, side plates, and angles with proper stiffening bars on the side plates, or "I's," or lattice, or other forms of truss work. In girders and beams the maximum fibre stress is usually limited to 16,000 ℔. In very short girders the shear must be computed, and in long girders the deflexion, particularly the flexure from the variable load, since a flexure of more than $\frac{1}{500}$ of the length is liable to crack the plastering of the ceilings carried by the girders. The same necessity for computing shear and flexure applies to the floor beams. The floors between the girders are constructed of "I" beams, spaced generally about 5 ft. between centres; their ends are usually framed to fit the form of the girders, and rest either upon their lower flanges, or upon seats formed of angles riveted to their webs, being secured to them by a pair of angles at each end of the beam riveted to its web and to the web of the girder. Sometimes the beams rest upon the girders, and are riveted through the flanges to it; in this case the abutting ends of beams are spliced by scarf plates placed on each side of the webs and secured by rivets. A similar construction is followed for flat roofs, the grades being generally formed in the girder and beam construction, and a flat ceiling secured by hanging from them, with steel straps, a light tier of ceiling beams. The floor beams are tied laterally by rods in continuous lines placed at or above their neutral axis. It is usual in both girders and beams to provide not only for the safe support of the greatest possible distributed load, but for the greatest weight, such as that of a safe or other heavy piece of furniture which may be moved over the floor at its weakest points, the centres of the girders and beams. It must always be borne in mind that the formulae for the ultimate strength of the "I" beams only hold good when the upper chord or flange is supported laterally.

Considerable improvement has been made in the design of rolled steel shapes; for example the rolling of a 16-in. joist was formerly deemed a remarkable achievement, though now there are several works producing 24-in. joists with flanges 7 and $7\frac{1}{2}$ in. wide. The Broad Flange Differdange Beams are claimed by the manufacturers to be stronger and to minimize weight for use as girders; they are made in twenty-one different sizes with flanges from $8\frac{5}{8}$ to 12 in. wide.

The introduction of steel construction has simplified many details of architectural treatment, such as projections for cornices, bay windows and galleries. These may be supported by bracket-angles attached to the columns with a system of anchors to tie them back; the material must be carried in such a manner as to make it independent of the general structure, and must be constructed as light as possible. If the supporting member is a floor beam or girder the girder should be rigidly connected to the floor system to prevent any twisting due to the weight of the projection.

Floors. The arrangement of the building and floor framings is in a great measure governed by the architectural effect sought and by the arrangement and proper planning of the interior according to the intended uses; the positions of columns, girders and floor beams are usually the result of particular requirements, and unless complicated and expensive framing is to be expected the distance between columns must be kept within the limits of simple girder construction. The position of the columns having been determined, the girders must next be located; these serve to support the floor beams which transfer the loads direct to the columns, and also to brace the columns during erection. The spacing, or distance from centre to centre of the floor beams, will depend upon the type of fire-proof flooring employed; it also depends to a considerable extent upon the amount and character of the floor load and the length of span. If the loads to be carried are largely stationary, and if the span is small, the floor joists can be readily proportioned by means of tables given in the handbooks issued by many steel companies. The distance between joists should be limited to 5 or 6 ft.; horizontal bracing by means of diagonal rods is sometimes used, but should be avoided. The following are the usual assumptions made in good practice for superimposed loads:—

Floors of dwellings and offices	70 ℔ per sq. ft.
,, ,, churches, theatres and ball-rooms	125 ,, ,, ,, ,,
,, ,, warehouses	200 to 250 ,, ,, ,, ,,
,, ,, for heavy machinery	250 to 400 ,, ,, ,, ,,

Wind-bracing. The relation between the velocity of wind and the pressure exerted upon surfaces must be considered in steel construction, and designers differ in regard to the forces to be resisted and the material to be used. Every building offers its own peculiar condition; the height, width, shape and situation of the structure, and character of the enclosing walls, will determine the amount of wind pressure to be provided against, and the internal appearance and the planning of the various floors will largely influence the manner in which the bracing is to be treated. There are many and varied forms of bracing, each designer adopting methods peculiar to his own ideas. One form consists of adjustable diagonals, rods or bars, properly fastened to the columns in the building; these diagonals may run through one floor and be attached to the columns at the floor above. Another form is known as portal bracing; this is usually braced between adjacent columns in halls or passage-ways and extends from the foundations up from floor to floor to such a height that the stability of the building itself is sufficient to resist the assumed wind pressure. In general, if the building is square or nearly so wind-bracing should be placed close to the corners. In case neither of the above methods can be applied, brackets should be used at each floor level or a continuous deep beam or girder carried all around the building. Some architects depend solely upon partitions, and a building with a well-constructed iron frame should be safe if provided with brick partitions or if the exterior of the iron framework is covered with well-built masonry of sufficient thickness.

Truss rods, portals, or lattice or plate girders constitute the more definite types of wind-bracing ordinarily employed; the bracing must reach to some solid connexion at the ground. The greatest wind pressure to which a building is subjected is that from a horizontal wind. The maximum pressure is not uniform from the ground level to the roof but is greatest at the centre; it is diminished near the ground level by the frictional resistance of the ground, and at the eaves by the eddies formed by the air escaping over the roof. The change in direction of the air when striking a flat surface such as the side of a building will form a cushion to diminish the effects of impulses and shocks from local gusts.

The building laws of the city of New York require the following provisions as regards wind forces:—

"All structures exposed to wind shall be designed to resist a horizontal wind pressure of thirty pounds for every square foot of surface thus exposed, from the ground to the top of the same, including roof, in any direction. In no case shall the overturning moment due to wind pressure exceed seventy-five per centum of the moment of stability of the structure. In all structures exposed to wind, if the resisting moments of the ordinary materials of construction, such as masonry, partitions, floors and connexions, are not sufficient to resist the moment of distortion due to wind pressure, taken in any direction on any part of the structure, additional bracing shall be introduced sufficient to make up the difference in the moments. In calculations for wind pressures, the working stresses set forth in the code may be increased by fifty per centum. In buildings under one hundred feet in height, provided the height does not exceed four times the average width of the base, the wind pressure may be disregarded."

Materials Used. The steel used throughout the entire structure should be subjected to the most thorough chemical and mechanical tests and inspection, first at the mill and subsequently at the fabricating shops and the building, to ensure that it shall not contain more than 0·08% of phosphorus or 0·06% of sulphur, that it shall have an ultimate strength of between 60,000 and 70,000 ℔ per sq. in., with an elastic limit of not less than 35,000 ℔ per sq. in., and an elongation before fracture of not less than 25% in 8 in. of length, and that a piece of the material may be bent cold 180° over a mandril equal to the thickness of the piece tested without fracture of the fibres on the outside of the bend. At least two pieces are taken from each melt or blow at the mill, and are stamped or marked, and all the various sections rolled from the melt or blow are required to bear a similar stamp or mark for identification. All finished material is carefully examined to see that it possesses a smooth surface, and that it is free from cracks, seams and other defects, and that it is true to section throughout. Rivets are either of wrought iron or of extra soft steel, with an ultimate tensile strength of 55,000 ℔ per sq. in. The material must be sufficiently tough to bend cold 180° flat on itself without sign of fracture. The greatest care is taken that no steel is left in a brittle condition by heating and cooling without proper annealing. All abutting joints in riveted work are faced to exact lengths and absolutely at right angles to the axis of the piece, and are spliced by scarf plates of proper dimensions adequately secured by rivets. The work should be so accurate that no packing pieces are necessary. If the conditions are such that a packing or filling piece must be used, the end of one piece is cut to a new and true surface, and the filling piece is planed to fill the space accurately. Where cast iron is used it must be of tough grey iron free from defects. In testing it pieces 14 in. long and 1 in. square are cast from each heat and supported on blunt knife edges spaced 12 in. apart; under a load in the centre of the piece of 2500 ℔ the deflexion must not exceed $\frac{3}{16}$ in.

Floor-filling and Partitions. The filling between the girders and floor beams consists of segmental arches of brick, segmental or flat arches of porous (sawdust) terra-cotta, or hard-burned hollow terra-cotta voussoirs, or various patented forms of concrete floors containing ties or supports of steel or iron. In all cases it is customary to fill on top of the arches with a strong Portland cement concrete to a uniform level, generally the top of the deepest beam; the floor filling is constructed and carried to this level immediately upon the completion of each tier of beams, for the purpose not only of stiffening the frame laterally, and of adding to its stability by the imposition of a static load, but also to afford constantly safe and strong working platforms at regular and convenient intervals for use throughout the entire period of the construction. In cases in which the lateral rigidity of the floors is depended upon to transfer the horizontal strains to the exterior walls which are framed to resist them, no form of floor construction should be used which is not laterally strong and rigid. With very rapid building, no method of construction of floors furrings, or partitions should be adopted which will not dry out with great speed. In flat forms of masonry floor construction the level of its bottom is placed somewhat below the bottom of the "I" beams and girders, so that when it is plastered a continuous surface of at least an inch of mortar will form a fire-proof protection for the lower flanges of the beams and girders. Where the width of the flange is considerable it is first covered with metal lath secured to the under side of the floor masonry. Girders projecting below the floor are usually encased in from 1 to 2 in. of fire-proof material, 2 or 4 in. of which is also put on all columns. Such fire-proof coverings, and also interior partitions, are composed of hollow, hard-burned terra-cotta blocks, of porous (sawdust) terra cotta, or various plastic compositions applied to metallic lath, many of which are patented both as to material and method of application. The most simple test for the value of a system of fire-proof coverings, and of partitions and furrings, is to erect a large sample of the work and to subject it alternately to the continued action of an intensely hot flame which is allowed to impinge upon it, and to a stream of cold water directed upon it from the ordinary service nozzle of a steam fire engine. It is important in all fire-proofing of columns and girders, and in all floor construction, furring and partitions, that there shall be no continuous voids, either vertical or horizontal, which may possibly serve as flues for the spread of heat or flame in case of fire. All furrings and partitions must be started on the solid masonry of the floors to prevent the possible passage of fire from the room in which it may occur. The failure to make this provision has been the cause of very serious losses in buildings which were supposed to be fire-proof.

Time and Cost of Erection. Steel construction possesses great advantages in time required for erection. When once the site is cleared and the foundations prepared and set, work can be pushed on the walls at different storeys at one and the same time, and often main cornices and filling-in work are fixed before special details and ornamentation. In the Commercial Cable Building, New York, seven complete tiers aggregating 7000 tons were erected in nine weeks. In the Unity Building, Chicago, of seventeen storeys, the metal framework from basement columns to finished roof was accomplished in nine weeks. In the Fisher Building, Chicago, the entire steel skeleton above the first floor, nineteen storeys and attic, was erected in twenty-six days.

Owing to the low price of steel it is possible to make a steel column of equivalent strength cheaper than one in cast iron. The question of cost is purely a commercial one, but the cost of the raw material will practically never determine the relative cost between various forms, as the expense of manufacture and the detail and duplication of members will all influence the ultimate cost to a much greater extent than the simple cost of the plain materials. The steelwork for a building of any considerable size is almost invariably rolled to order.

Steel construction and the rapid development of engineering practice has affected not only the erection of tall buildings, but has also produced improvement in the erection of factory and workshop premises. Modern workshops consist of wider buildings of greater height with plenty of roof-light, efficient ventilation, and artificial heating, and as the heavy loads can be carried by the reinforcing material, heavy walls become unnecessary. Gradually, therefore, the modern steel-framed factory has been evolved, capable of supporting all the loads, the outer walls being required only for protection against weather. Light steel roof trusses have replaced the timber trusses, and with the columns form a rigid framework to resist the structural and wind loads as well as those from the cranes and shafting.

Factory Buildings.

In Germany skeleton steel-framed factory buildings may be erected with half brick (12 cm.), with a restriction that when such buildings are abutting or are in the immediate neighbourhood, *i.e.* within 20 ft. of a neighbouring building, the outside walls on the sides affected shall be full brick (25 cm.).

The permissible height to which a building may be erected on the continent of Europe depends largely on the breadth of the road on which such buildings are situated. As a rule it is not permissible to erect a building wider than the road, measured from building line to building line.

In American practice the use of steel in buildings of ten or more storeys, or in manufacturing plant where the floor loads are heavy and frequently "live" in the sense of causing vibration, has led to more careful specifications as to the quality of materials and character of workmanship, and it is the custom of the leading architects to have the structural frame inspected and tested during manufacture at the foundries, rolling-mills and shops by a firm of engineers making a speciality of such inspections.

The illustrations (see Plates I. and II.) will give a good idea of the general construction as now carried out in England and America.

STEELE, ANNE (1717–1778), English hymn writer, was born at Broughton, Hampshire, in 1717. The drowning of her betrothed a few hours before the time fixed for her marriage deeply affected an otherwise quiet life, and her hymns rather emphasize the less optimistic phases of Christian experience. In 1760 she published *Poems on Subjects Chiefly Devotional* under the name "Theodosia," and her complete works (144 hymns, 34 metrical psalms and 50 moral poems) appeared in one volume in London (1863). She was a Baptist, and her hymns are much used by members of that communion, though some of them, *e.g.* "Father of mercies, in Thy word," have found their way into the collections of other Churches. She has been called the Frances Ridley Havergal of the 18th century.

STEELE, SIR RICHARD (1672–1729), English man of letters in the reign of Queen Anne, is inseparably associated in the history of literature with his personal friend Addison. He cannot be said to have lost in reputation by the partnership, because he was inferior to Addison in purely literary gift, and it is Addison's literary genius that has floated their joint work above merely journalistic celebrity; but the advantage was not all on Steele's side, inasmuch as his more brilliant coadjutor has usurped not a little of the merit rightly due to him. Steele's often-quoted generous acknowledgment of Addison's services in the *Tatler* has proved true in a somewhat different sense from that intended by the writer: "I fared like a distressed prince who calls in a powerful neighbour to his aid; I was undone by my auxiliary; when I had once called him in I could not subsist without dependence on him." The truth is that in this happy alliance the one was the complement of the other; and the balance of mutual advantage was much more nearly even than Steele claimed or posterity has generally allowed.

The famous literary pair were born in the same year. Steele, the senior by less than two months, was baptized on the 12th of March 1672 in Dublin. His father, also Richard Steele, was an attorney. He died before his son had reached his sixth year, but the boy found a protector in his maternal uncle, Henry Gascoigne, secretary and confidential agent to two successive dukes of Ormond. Through his influence he was nominated to the Charterhouse in 1684, and there first met with Addison. Five years afterwards he proceeded to Christ Church, Oxford, and was a postmaster at Merton when Addison was a demy at Magdalen. Their schoolboy friendship was continued at the university, and probably helped to give a more serious turn to Steele's mind than his natural temperament would have taken under different companionship. Addison's father also took an interest in the warm-hearted young Irishman; but their combined influence did not steady him sufficiently to keep his impulses within the lines of a regular career; without waiting for a degree he volunteered into the army, and served for some time as a cadet "under the command of the unfortunate duke of Ormond" (*i.e.* the first duke's grandson, who was attainted in 1715). This escapade was made without his uncle's consent, and cost him, according to his own account, "the succession to a very good estate in the county of Wexford in Ireland." Still, he did not lack advancement in the profession he had chosen. A poem on the funeral of Queen Mary (1695), dedicated to Lord Cutts, colonel of the Coldstream Guards, brought him under the notice of that nobleman, who took the gentleman trooper into his household as a secretary, made him an officer in his own regiment, and ultimately procured for him a captaincy in Lord Lucas's regiment of foot. His name was noted for promotion by King William, but the king's death took place before anything had been done for Captain Steele. A duel which he fought with Captain Kelly in Hyde Park in 1700, and in which he wounded his antagonist dangerously, inspired him with the dislike of the practice that he showed to the end of his life.

Steele probably owed the king's favour to a timely reference to his majesty in *The Christian Hero*, his first prose treatise, published in April 1701. The "reformation of manners" was a cherished purpose with King William and his consort, which they tried to effect by proclamation and act of parliament; and a sensible well-written treatise, deploring the irregularity of the military character, and seeking to prove by examples—the king himself among the number—"that no principles but those of religion are sufficient to make a great man," was sure of attention. Steele complained that the reception of *The Christian Hero* by his comrades was not so respectful; they persisted in trying him by his own standard, and would not pass "the least levity in his words and actions" without protest. His uneasiness under the ridicule of his irreverent comrades had a curious result: it moved him to write a comedy. "It was now incumbent upon him," he says "to enliven his character, for which reason he writ the comedy called *The Funeral*." Although, however, it was Steele's express purpose to free his character from the reproach of solemn dullness, and prove that he could write as smartly as another, he showed greater respect for decency than had for some time been the fashion on the stage. The purpose, afterwards more fully effected in his famous periodicals, of reconciling wit, good humour and good breeding with virtuous conduct was already deliberately in Steele's mind when he wrote his first comedy. It was produced and published in 1701, and received on the stage with favour. In his next comedy, *The Lying Lover; or, the Ladies' Friendship*, based on Corneille's *Menteur*, produced two years afterwards, in December 1703, Steele's moral purpose was directly avowed, and the play, according to his own statement, was "damned for its piety." *The Tender Husband*, an imitation of Molière's *Sicilien*, produced eighteen months later (in April 1705), though not less pure in tone, was more successful; in this play he gave unmistakable evidence of his happy genius for conceiving and embodying humorous types of character, putting on the stage the parents or grandparents of Squire Western, Tony Lumpkin and Lydia Languish. It was seventeen years before Steele again tried his fortune on the stage with *The Conscious Lovers*, the best and most successful of his comedies, produced in December 1722.

Meanwhile the gallant captain had turned aside to another kind of literary work, in which, with the assistance of his friend Addison, he obtained a more enduring reputation. There never was a time when literary talent was so much sought after and rewarded by statesmen. Addison had already been waited on in " his humble lodgings in the Haymarket," and advanced to office, when his friend the successful dramatist was appointed to the office of gazetteer. This was in April or May 1707. It was Steele's first connexion with journalism. The periodical was at that time taking the place of the pamphlet as an instrument for working on public opinion. The *Gazette* gave little opening for the play of Steele's lively pen, his main duty, as he says, having been to " keep the paper very innocent and very insipid "; but the position made him familiar with the new field of enterprise in which his inventive mind soon discerned materials for a project of his own. The *Tatler* made its first appearance on the 12th of April 1709. It was partly a newspaper, a journal of politics and society, published three times a week. Steele's position as gazetteer furnished him with special advantages for political news, and as a popular frequenter of coffee-houses he was at no loss for social gossip. But Steele not only retailed and commented on social news, a function in which he had been anticipated by Defoe and others; he also gradually introduced into the *Tatler* as a special feature essays on general questions of manners and morality. It is not strictly true that Steele was the inventor of the English " essay "—there were essayists before the 18th century, notably Cowley and Temple; but he was the first to use the essay for periodical purposes, and he and Addison together developed a distinct species, to which they gave a permanent character, and in which they had many imitators. As a humbler motive for this fortunate venture Steele had the pinch of impecuniosity, due rather to excess of expenditure than to smallness of income. He had £300 a year from his gazetteership (paying a tax of £45), £100 as gentleman waiter to Prince George, £850 from the Barbadoes estates of his first wife, a widow named Margaret Stretch, and some fortune by his second wife—Mrs Mary Scurlock, the " dear Prue " of his charming letters. But Steele lived in considerable state after his second marriage, and before he started the *Tatler* was reduced to the necessity of borrowing. The assumed name of the editor was Isaac Bickerstaff, but Addison discovered the real author in the sixth number, and began to contribute in the eighteenth. It is only fair to Steele to state that the success of the *Tatler* was established before Addison joined him, and that Addison contributed to only forty-two of the two hundred and seventy-one numbers that had appeared when the paper was stopped, obscurely, in January 1711. Some papers satirizing Harley appeared in the *Tatler*, and Steele lost or resigned the post of gazetteer. It is possible that this political recklessness may have had something to do with the sudden end of the venture.

Only two months elapsed between the stoppage of the *Tatler* and the appearance of the *Spectator*, which was the organ of the two friends from the 1st of March 1711 till the 6th of December 1712. Addison was the chief contributor to the new venture, and the history of it belongs more to his life. Nevertheless, it is to be remarked as characteristic of the two writers that in this as in the *Tatler* Addison generally follows Steele's lead in the choice of subjects. The first suggestion of Sir Roger de Coverley was Steele's although it was Addison that filled in the outline of a good-natured country gentleman with the numerous little whimsicalities that convert Sir Roger into an amiable and exquisitely ridiculous provincial oddity. Steele had neither the fineness of touch nor the humorous malice that gives life and distinction to Addison's picture; the Sir Roger of his original hasty sketch has good sense as well as good nature, and the treatment is comparatively commonplace from a literary point of view, though unfortunately not commonplace in its charity. Steele's suggestive vivacity gave many another hint for the elaborating skill of his friend.

The *Spectator* was followed by the *Guardian*, the first number of which appeared on the 12th of March 1713. It had a much shorter career, extending to only a hundred and seventy-six numbers, of which Steele wrote eighty-two. This was the last of his numerous periodicals in which he had the material assistance of Addison. But he continued for several years to project journals, under various titles, some of them political, some social in their objects, most of them very short-lived. Steele was a warm partisan of the principles of the Revolution, as earnest in his political as in his other convictions. The *Englishman* was started in October 1733, immediately after the stoppage of the *Guardian*, to assail the policy of the Tory ministry. The *Lover*, started in February 1714, was more general in its aims; but it gave place in a month or two to the *Reader*, a direct counterblast to the Tory *Examiner*. The *Englishman* was resuscitated for another volume in 1715; and he subsequently projected in rapid succession three unsuccessful ventures—*Town Talk*, the *Tea Table* and *Chit Chat*. Three years later he started his most famous political paper the *Plebeian*, rendered memorable by the fact that it embroiled him with his old ally Addison. The subject of controversy between the two lifelong friends was Sunderland's Peerage Bill. Steele's last venture in journalism was the *Theatre*, 1720, the immediate occasion of which was the revocation of his patent for Drury Lane. Besides these journals he wrote also several pamphlets on passing questions—on the disgrace of Marlborough in 1711, on the fortifications of Dunkirk in 1713, on the " crisis " in 1714, *An Apology for Himself and his Writings* (important biographically) in the same year, and on the South Sea mania in 1720.

The fortunes of Steele as a zealous Whig varied with the fortunes of his party. Over the Dunkirk question he waxed so hot that he threw up a pension and a commissionership of stamps, and went into parliament as member for Stockbridge to attack the ministry with voice and vote as well as with pen. But he had not sat many weeks when he was expelled from the house for the language of his pamphlet on the *Crisis*, which was stigmatized as seditious. The *Apology* already mentioned was his vindication of himself on this occasion. With the accession of the House of Hanover his fortunes changed. Honours and substantial rewards were showered upon him. He was made a justice of the peace, deputy-lieutenant of Middlesex, surveyor of the royal stables, governor of the royal company of comedians—the last a lucrative post—and was also knighted (1715). After the suppression of the Jacobite rebellion he was appointed one of the commissioners of forfeited estates, and spent some two years in Scotland in that capacity. In 1718 he obtained a patent for a plan for bringing salmon alive from Ireland. Differing from his friends in power on the question of the Peerage Bill he was deprived of some of his offices, but when Walpole became chancellor of the exchequer in 1721 he was reinstated. With all his emoluments however the imprudent, impulsive, ostentatious and generous Steele could never get clear of financial difficulties, and he was obliged to retire from London in 1724 and live in the country. He spent his last years on his wife's estate of Llangunnor in Wales, and, his health broken down by a paralytic seizure, died at Carmarthen on the 1st of September 1729.

A selection from Steele's essays, with a prefatory memoir, has been edited by Mr Austin Dobson (1885; revised 1896). Mr Dobson contributed a fuller biography to Mr Andrew Lang's series of *English Worthies*, in 1886. In 1889 another and more exhaustive life was published by Mr G. A. Aitken, who has also edited Steele's plays (1898) and the *Tatler* (1898). (W. M.; A. D.)

STEELE, THOMAS (1788–1848), Irish politician and writer, a member of a Somerset family which settled in Ireland during the 17th century, was born on the 3rd of November 1788. He was educated at Trinity College, Dublin, and at Magdalene College, Cambridge, and succeeded to a large estate in Co. Clare. As a volunteer he fought against the Bourbons in Spain in 1823, and, returning to Ireland, he became an enthusiastic worker for Roman Catholic emancipation, helping greatly to return Daniel O'Connell to parliament for Co. Clare at the famous election of 1828. It is interesting to note that Steele himself was a Protestant. Having ruined his fortune by contributing liberally to the causes in which he was interested, he died in London on the 15th of June 1848. He wrote *Notes of the War in Spain* (1824) and some essays on Irish questions.

STEELE, WILLIAM (d. 1680), lord chancellor of Ireland, was a son of Richard Steele of Sandbach, Cheshire, and was educated at Caius College, Cambridge. In 1648 he was chosen recorder of London, and he was one of the four counsel appointed to conduct the case against Charles I. in January 1649, but illness prevented him from discharging this duty. However, a few days later he took part in the prosecution of the duke of Hamilton and other Royalists. Steele was M.P. for the City of London in 1654, was chief baron of the exchequer in 1655, and was made lord chancellor of Ireland in 1656. After the fall of Richard Cromwell he was one of the five commissioners appointed in 1659 to govern Ireland. At the end of this year he returned to England, but he refused to sit on the committee of safety to which he had been named. At the Restoration he obtained the full benefits of the Act of Indemnity, but he thought it advisable to reside for a time in Holland. However, he had returned to England before his death towards the end of 1680.

See O. J. Burke, *History of the Lord Chancellors of Ireland* (Dublin, 1879).

STEELE, a town of Germany, in the Prussian Rhine Province on the navigable Ruhr, 4 m. by rail E. of Essen, at the junction of the lines Duisburg-Dortmund and Vohwinkel-Hagen. Pop. (1905), 12,988. It contains a Gothic parish church (Roman Catholic), a high school and a Roman Catholic hospital. It has coal-mines, iron and steel works, and makes fireproof bricks. A Diet of the empire was held here in the year 938 by the emperor Otto I.

STEELTON, a borough of Dauphin county, Pennsylvania, U.S.A., on the Susquehanna river, 3 m. S.E. of Harrisburg. Pop. (1890), 9250; (1900), 12,086, of whom 2300 were foreign-born and 1508 were negroes; (1910 census), 14,246. Steelton is served by the Pennsylvania and the Philadelphia & Reading railways, and is connected with Harrisburg by electric line. The city has a public library. Steelton is in an agricultural district, but its industrial importance is due primarily to the vast steel works of the Pennsylvania Steel Company. Other manufactures are flour and grist mill products, bricks, planing-mill products, &c. In 1905 the total value of the borough's factory products was $15,745,628; the capital invested in manufacturing increased from $6,266,068 in 1900 to $18,642,853 in 1905, or 197·5%. There is a large limestone quarry within the borough limits. The municipality owns its waterworks and filtration plant. The place was laid out in 1866 under the name of Baldwin, but when it was incorporated as a borough, in 1880, the present name was adopted.

STEELYARD, MERCHANTS OF THE, Hanse merchants who settled in London in 1250 at the steelyard on the river-side, near Cosin Lane, now Ironbridge Wharf. Henry III. in 1259, at the request of his brother Richard of Cornwall, king of the Romans, conferred on them important privileges, which were confirmed by Edward I. It was chiefly through their enterprise that the early trade of London was developed, and they continued to flourish till, on the complaint of the Merchant Adventurers in the reign of Edward VI., they were deprived of their privileges. Though Hamburg and Lübeck sent ambassadors to intercede for them, they were not reinstated in their monopolies, but they succeeded in maintaining a footing in London till expelled by Elizabeth in 1597. Their beautiful guildhall in Thames Street, adorned with allegorical pictures by Holbein, and described by Stow, was made a naval storehouse. The land and buildings still remained the property of the Hanseatic League, and were subsequently let to merchants for business purposes. Destroyed in the Great Fire of 1666 they were rebuilt as warehouses, and were finally sold to the South-Eastern Railway Company in 1852 by the Hanseatic towns, Lübeck, Bremen and Hamburg. The site is now occupied by Cannon Street railway station.

See Lappenburg, *Urkundliche Geschichte des hansischen Stahlhofes zu London* (Hamburg, 1851); Stow, *Survey of London* (1598); Pauli, *Pictures of Old London* (1851); Ehrenberg, *Hamburg und England im Zeitalter der Königin Elizabeth* (Jena, 1896).

STEEN, JAN HAVICKSZ (1626–1679), Dutch subject-painter, was born at Leiden in 1626, the son of a brewer of the place. He studied at Utrecht under Nicolas Knupfer, a German historical painter. Dr Bode suggests that, before entering Knupfer's studio, Jan Steen took drawing lessons from Jacob de Wet in Haarlem. He bases his theory on the internal evidence of such early pictures as the "Market at Leiden" (Staedel Institute, Frankfort), the "Kermesse" (A. von Goldschmidt-Rothschild, Berlin), "Calling for the Bride" (Six Collection, Amsterdam), and "St John's Sermon" (Dessau Castle). About the year 1644 Steen went to Haarlem, where he worked under Adrian van Ostade and under Jan van Goyen, whose daughter he married in 1649. In the previous year he had joined the painters' gild of the city. In 1667 he is said to have been a brewer at Delft; in 1669 a small debt of ten florins owing to an apothecary led to the seizure and sale of his pictures, and in 1672 he received municipal authority to open a tavern. In 1673 he took a second wife, Maria van Egmont, the widow of a bookseller in Leiden. The accounts of his life, however, are very confusing and conflicting. Some biographers have asserted that he was a drunkard and of dissolute life, but the number of his works—Van Westrheene, in his *Jan Steen, étude sur l'art en Holland*, has catalogued nearly five hundred and Hofstede de Groot about double that number—seems sufficient in itself to disprove the charge. His later pictures bear marks of haste and are less carefully finished than those of his earlier period. He died at Leiden in 1679.

The works of Jan Steen are distinguished by correctness of drawing, admirable freedom and spirit of touch, and clearness and transparency of colouring. But their true greatness is due to their intellectual qualities. In the wide range of his subjects, and their dramatic character, he surpasses all the Dutch figure-painters, with the single exception of Rembrandt. His productions range from the stately interiors of grave and wealthy citizens to tavern scenes of jollity and debauch. He painted chemists in their laboratories, doctors at the bedside of their patients, card-parties, marriage feasts, and the festivals of St Nicholas and Twelfth Night—even religious subjects, though in these he was least successful. His rendering of children is especially delightful. Dealing often with the coarser side of things, his work is full of humour; he depicts the comedy of human life in a spirit of very genial toleration, but now and again there appear keenly telling touches of satire which recall a pictorial moralist such as Hogarth. Portraits from his brush are comparatively rare. The best known is the portrait of himself at the Rijksmuseum in Amsterdam.

The National Gallery contains three pictures by Jan Steen, of which the "Music Master" is the most important, and other excellent examples of his art in England are preserved in the Royal, the Bute, and the Northbrook collections, at Apsley House and Bridgewater House, and in the galleries of the Hague, Amsterdam, and the Hermitage, St Petersburg. A remarkably fine example of his work, which appeared at the Royal Academy Winter Exhibition in 1907, is the "Grace Before Meat."

STEENKIRK (STEENKERKE), a village in the Belgian province of Hainaut, on the river Senne, famous for the battle of Steenkirk (Steinkirk, Estinkerke) fought on July 23rd/August 3rd 1692 between the Allies (see GRAND ALLIANCE, WAR OF THE) under William III. of England and the French commanded by the duke of Luxemburg. Previous to the battle the French army lay facing north-west, with its right on the Senne at Steenkirk and its left towards Enghien, while the army of William III. was encamped about Hal. In accordance with the strategical methods of the time, the French, not wishing to fight after having achieved the immediate object, the capture of Namur, took up a strong position, supposing the enemy would not dare to attack it, while the Allies, who would otherwise in all probability have done as the French marshal desired, were by the fortune of war afforded the opportunity of surprising a part of the enemy's forces. For in the 17th century, when the objects of a war were as far as possible secured without the loss of valuable lives, and general decisive battles were in every way considered undesirable, a brilliant victory over a part, not the whole, of the enemy's forces was the tactical idea of the best generals, and accordingly William, having completely misled the enemy by forcing a detected spy to give Luxemburg false news, set his army in motion before dawn on July 23rd/ August 3rd to surprise the French right about Steenkirk. The advanced guard of infantry and pioneers, under the duke of Württemberg, deployed close to the French camps ere Luxemburg became aware of the impending blow; at this moment the main body of the army farther back was forming up after the passage of some woods. When the fight opened, Luxemburg was completely surprised, and he could do no more than hurry the nearest foot and dragoons into action as each regiment came on the scene. But the march of the Allies' main body had been mismanaged; while Württemberg methodically cannonaded the enemy, waiting for support and for the order to advance, and the French worked with feverish energy to form a strong and well-covered line of battle at the threatened point, the Allies' main body, which had marched in the usual order, one wing of cavalry leading, the infantry following, and the other wing of cavalry at the tail of the column, was being hastily sorted out into infantry and cavalry, for the ground was only suitable for the former. A few battalions only had come up to support the advanced guard when the real attack opened (12.30). The advanced guard had already been under arms for nine hours, and the march had been over bad ground, but its attack swept the first French line before it. The English and Danes stubbornly advanced, the second and third lines of the French infantry giving ground before them, but Luxemburg was rapidly massing his whole force to crush them, and meanwhile the confusion in the allied main body had reached its height. Count Solms, who commanded it, ordered the cavalry forward, but the mounted men, scarcely able to move over the bad roads and heavy ground, only blocked the way for the infantry. Some of the English foot, with curses upon Solms and the Dutch generals, broke out to the front, and Solms, angry and excited, thereupon refused to listen to all appeals for aid from the front. No attempt was made to engage and hold the centre and left of the French army, which hurried, regiment after regiment, to take part in the fighting at Steenkirk. William's counter-order that the infantry was to go forward, the cavalry to halt, only made matters worse, and by now the advanced guard had at last been brought to a standstill. At the crisis Luxemburg had not hesitated to throw the whole of the French and Swiss guards, led by the princes of the royal house, into the fight, and as, during and after this supreme effort, more and more French troops appeared from the side of Enghien, the Allies were driven back, contesting every step by weight of numbers. Those troops of the main body, foot and dragoons, which succeeded in reaching the front, served only to cover and to steady the retreat of Württemberg's force, and, the *coup* having manifestly failed, William ordered the retreat. The Allies retired as they had come, their rear-guard showing too stubborn a front for the French to attack. The latter were indeed in no state to pursue. Over eight thousand men out of only about fifteen thousand engaged on the side of the Allies were killed and wounded, and the losses of the French out of a much larger force were at least equal. Contemporary soldiers affirmed that Steenkirk was the hardest battle ever fought by infantry, and the battle served not only to illustrate the splendid discipline of the old professional armies, but also to give point to the reluctance of the generals of those days to fight battles in which, once the fighting spirit was unchained, the armies shot each other to pieces before either would give way.

STEEPLE (akin to "steep"), a general architectural name (Fr. *clocher*, Ital. *campanile*, Ger. *Glockenturm*) for the whole arrangement of tower, belfry, spire, &c.

STEEPLECHASE, a variety of horse-racing not run on the flat, but either across country or on a made course with artificial fences, water-jumps, &c. (see HORSE-RACING). The origin of the sport and the name is due to matches run by owners of hunters, the goal being some prominent landmark, such as a neighbouring church steeple. There is an early record of such a match in 1752 in Ireland, when the course was 4½ m., "from the Church of Buttevaut to the spire of St Leger Church." The name is sometimes used of cross-country running or of a race on a made course over hurdles and other obstacles. It is also given to an English variation of the old French game of Goose (*q.v.*). It is played with two dice on a board, on which is depicted a race-course with hurdles, water-jumps and other obstacles. The course is marked in 60 compartments by means of radii, and the game is won by the player whose horse makes the circuit in the fewest throws. Each player is provided with a marker, usually in the form of a jockey on horseback, which is moved forward after each throw to the space to which the number thrown entitles it.

STEER, PAUL WILSON (1860–   ), English painter, was born at Birkenhead. He was trained first at the Gloucester school of art and afterwards in Paris at the Académie Julian, and in the École des Beaux Arts under Cabanel. After 1886, before which date he had shown three pictures at the Royal Academy, practically the whole of his work was seen in the exhibitions of the New English Art Club, of which he is a prominent member. His figure subjects and landscapes show great originality and technical skill (see PAINTING: *Recent British*). His portrait of himself is included in the collection in the Uffizi Gallery, Florence.

STEEVENS, GEORGE (1736–1800), English Shakespearian commentator, was born at Poplar on the 10th of May 1736, the son of an East India captain, afterwards a director of the company. He was educated at Eton and at King's College, Cambridge, where he resided from 1753 to 1756. Leaving the university without a degree, he settled in chambers in the Temple, removing later to a house on Hampstead Heath, where he collected a valuable library, rich in Elizabethan literature. He also accumulated a large collection of Hogarth prints, and his notes on the subject were incorporated in John Nichols's *Genuine Works of Hogarth*. He walked from Hampstead to London every morning before seven o'clock, discussed Shakespearian questions with his friend, Isaac Reed, and, after making his daily round of the booksellers' shops, returned to Hampstead. He began his labours as a Shakespearian editor with reprints of the quarto editions of Shakespeare's plays, entitled *Twenty of the Plays of Shakespeare* . . . (1766). Dr Johnson was impressed by the value of this work, and suggested that Steevens should prepare a complete edition of Shakespeare. The result, known as Johnson's and Steevens's edition, was *The Works of Shakespeare with the Corrections and Illustrations of Various Commentators* (10 vols., 1773), Johnson's contributions to which were very slight. This early attempt at a variorum edition was revised and reprinted in 1778, and further edited in 1785 by Isaac Reed; but in 1793 Steevens, who had asserted that he was now a "dowager-editor," was persuaded by his jealousy of Edmund Malone to resume his labours. The definitive result of his researches was embodied in an edition of fifteen volumes. He made changes in the text sometimes apparently with the sole object of showing how much abler he was as an emendator than Malone, but his wide knowledge of Elizabethan literature stood him in good stead, and subsequent editors have gone to his pages for parallel passages from contemporary authors. His deficiencies from the point of view of purely literary criticism are apparent from the fact that he excluded Shakespeare's sonnets and poems because, he wrote, "the strongest act of parliament that could be framed would fail to compel readers into their service." In the twenty years between 1773 and 1793 he was less harmlessly engaged in criticizing his fellows and playing malicious practical jokes on them. Dr Johnson, who was one of his stanchest friends, said he had come to live the life of an outlaw, but he was generous and to a small circle of friends civil and kind. He was one of the foremost in exposing the Chatterton-Rowley and the Ireland forgeries. He wrote an entirely fictitious account of the Java upas tree, derived from an imaginary Dutch traveller, which imposed on Erasmus Darwin, and he hoaxed the Society of Antiquaries with the tombstone of Hardicanute, supposed to have been dug up in Kennington, but really engraved with an Anglo-Saxon inscription of his own invention. He died at Hampstead on the 22nd of January 1800. A monument to his memory by Flaxman, with an inscription commemorating his Shakespearian labours, was erected in Poplar Chapel. The sale catalogue of his valuable library is in the British Museum.

Steevens's Shakespeare was re-issued by Isaac Reed in 1803, in 21 volumes, with additional notes left by Steevens. This, which is known as the "first variorum" edition, was reprinted in 1813. Steevens's notes are also incorporated in the edition of 1821, begun by Edmund Malone and completed by James Boswell the younger.

STEEVENS, GEORGE WARRINGTON (1869–1900), English journalist, was born at Sydenham, near London, on the 10th of December 1869, and was educated at the City of London School and Balliol College, Oxford, of which he was a scholar. He first began to write in undergraduate periodicals. In 1893 he was elected a fellow of Pembroke College, Oxford, and in the same year spent some time at Cambridge, editing a weekly periodical, the *Cambridge Observer*, and becoming a contributor to the *National Observer*, then edited by Mr W. E. Henley. He then married and went to London, and joined the staff of the *Pall Mall Gazette*, contributing also to the *New Review* and *Blackwood's Magazine*. Some of his articles were reprinted in *Monologues of the Dead*. In 1896 he joined the staff of the London *Daily Mail*, then just started, and went on various special missions for that paper, which resulted in more than one series of articles, afterwards turned into books. In this way he published *The Land of the Dollar* (1897), *With the Conquering Turk* (1897), *Egypt in 1898*, and *With Kitchener to Khartoum* (1899). In September 1899 he went to South Africa and joined Sir George White's force in Natal as war-correspondent, being subsequently besieged in Ladysmith. He died during the siege, of enteric fever, on the 15th of January 1900. The articles he had sent home from South Africa were published posthumously in a volume called *From Capetown to Ladysmith*. Steevens had a remarkable gift of seizing the salient facts and principal characteristics in anything he wished to describe, and putting them in a vivid and readable way. His early death removed an interesting personality in English journalism.

STEFANIE, BASSO NAEBOR, or CHUWAHA, a lake of East Africa, lying in 37° E., between 4°25′ and 5° N., and measuring some 40 m. by 15. It is the southernmost and lowest (1880 ft.) of a series of lakes which lie in what appears to be a north-easterly continuation of the great East African rift valley, although this loses its clearly marked character in about 3° N. There is, however, a well defined watershed extending from the hills east of Stefanie to the Harrar range. The character of the lake, which has no outlet, varies greatly according to the amount of water brought down by its principal feeder, the Dulei, which enters at its north end, being there a fairly rapid stream 50 yds. wide and 3½ ft. deep. At low water the western part of the lake is dry. The Dulei, which rises north of 6° N., is joined in about 36° 55′ E., 5° 8′ N. by the Galana Sagan or Galana Amara. The Sagan in times of flood receives the overflow of the next lake in the series, Chambo or Ganjule, which lies, at a height of 3460 ft., 70 m. north-north-east of Stefanie. Chambo in turn receives the waters of a larger lake—Abai, Abaya, Pagade or Regina Margherita—through the river Walo, across a plain only 2 m. wide. Abai lies 4200 ft. above the sea, is 45 m. long and 18 m. across at its greatest width. It is cut by 38° E. There are a number of islands on the lake. All the lakes of the series are shut in by high mountains, those surrounding Lake Abai, together with the islands with which its surface is broken, being clothed with luxuriant vegetation. The chief feeder of Abai, the Bilate, rises in about 8° N. North-east of Abai are several smaller lakes unconnected with the more southerly system.

Lake Stefanie was discovered by Count Samuel Teleki in 1881, and has since, with others of the series, been explored by Donaldson Smith, V. Bottego, M. S. Welby, Oscar Neumann and others. J. J. Harrison in 1899 found the lake quite dried up, and two years later Count Wickenburg found water only in the northern part. An agreement of 1907 with Great Britain recognized the lake as within the Abyssinian Empire.

See *Geographical Journal* (Sept. 1896, Sept. and Dec. 1900, Sept. 1901, Oct. 1902). L. von Höhnel, *Discovery of Lakes Rudolf and Stefanie* (London, 1894); L. Vannutelli and C. Citerni, *L'Omo* (Milan, 1899); British War Office map, Africa, sheet 79.

STEFFANI, AGOSTINO (1653–1728), Italian ecclesiastic, diplomatist and musical composer, was born at Castelfranco on the 25th of July 1653. At a very early age he was admitted as a chorister at St Mark's, Venice. In 1667 the beauty of his voice attracted the attention of Count Tattenbach, by whom he was taken to Munich, where his education was completed at the expense of Ferdinand Maria, elector of Bavaria, who appointed him "Churfürstlicher Kammer- und Hofmusikus" and granted him a liberal salary. After receiving instruction from Johann Kaspar Kerl, in whose charge he lived, he was sent in 1673 to study in Rome, where Ercole Bernabei was his master, and among other works he composed six motets, the original manuscripts of which are now in the Fitzwilliam Museum at Cambridge. On his return to Munich in 1674 he published his first work, *Psalmodia vespertina*, a part of which was reprinted in Martini's *Saggio di contrappunto* in 1674. In 1675 he was appointed court organist. The date when he was ordained priest, with the title of Abbate of Lepsing, is not precisely known. His ecclesiastical status did not prevent him from turning his attention to the stage, for which, at different periods of his life, he composed work which undoubtedly exercised a potent influence upon the dramatic music of the period. Of his first opera, *Marco Aurelio*, written for the carnival and produced at Munich in 1681, the only copy known to exist is a manuscript score preserved in the royal library at Buckingham Palace. It was followed by *Solone* in 1685, by *Audacia e rispetto, prerogative d'amore* and *Servio Tullio* in 1686, by *Alarico* in 1687, and by *Niobe* in 1688; but of these works no trace can now be discovered. Notwithstanding the favour shown to him by the elector Maximilian Emanuel, he accepted in 1688 the appointment of Kapellmeister at the court of Hanover, where he speedily improved an acquaintance dating from 1681 with Ernest Augustus, duke of Brunswick-Luneburg (afterwards elector of Hanover), winning also a pleasant footing with the duchess Sophia Charlotte (afterwards electress of Brandenburg), the philosopher Leibnitz, the Abbate Ortensio Mauro, and many men of letters and intelligence, and where, in 1710, he showed great kindness to Handel, who was then just entering upon his glorious career. He inaugurated a long series of triumphs in Hanover by composing, for the opening of the new opera house in 1689, an opera called *Enrico il Leone*, which was produced with extraordinary splendour and achieved an immense reputation. For the same theatre he composed *La Lotta d'Ercole con Achilleo* in 1689, *La Superbia d'Alessandro* in 1690, *Orlando generoso* in 1691, *Le Rivali concordi* in 1692, *La Libertà contenta* in 1693, *I Trionfi del fato* and *I Baccanali* in 1695, and *Briseide* in 1696. The libretto of *Briseide* is by Palmieri. Those of most if not all the others are by the Abbate Mauro. The scores are preserved at Buckingham Palace, where, in company with five volumes of songs and three of duets, they form part of the collection brought to England by the elector of Hanover in 1714. But it was not only as a musician that Steffani distinguished himself in his new home. The elevation of Ernest Augustus to the electorate in 1692 led to difficulties, for the arrangement of which it was necessary that an ambassador should visit the various German courts, armed with a considerable amount of diplomatic power. The accomplished abbate was sent on this delicate mission in 1696, with the title of envoy extraordinary, and he fulfilled his difficult task so well that Pope Innocent XI., in recognition of certain privileges he had secured for the Hanoverian Catholics, consecrated him bishop of Spiga in the Spanish West Indies.

In 1698 he was sent as ambassador to Brussels, and after the death of Ernest Augustus in the same year he entered the service of the elector palatine, John William, at Düsseldorf, where he held the offices of privy councillor and protonotary of the holy see. Invested with these high honours, Steffani could scarcely continue to produce dramatic compositions in public without grievous breach of etiquette. But his genius was too importunate to submit to repression; and in 1709 he ingeniously avoided the difficulty by producing two new operas—*Enea* at Hanover and *Tassilone* at Düsseldorf—in the name of his secretary and amanuensis Gregorio Piva, whose signature is attached to the scores preserved at Buckingham Palace. Another score—that of *Arminio*—in the same collection, dated Düsseldorf, 1707, and evidently the work of Steffani, bears no composer's name.

Steffani did not accompany the elector George to England; but in 1724 the Academy of Antient Musick in London elected him its honorary president for life; and in return for the compliment he sent the association a magnificent *Stabat Mater*, for six voices and orchestra, and three fine madrigals. The manuscripts of these are still in existence, and the British Museum possesses a very fine *Confitebor*, for three voices and orchestra, of about the same period. All these compositions are very much in advance of the age in which they were written; and in his operas Steffani shows an appreciation of the demands of the stage very remarkable indeed at a period at which the musical drama was gradually approaching the character of a merely formal concert, with scenery and dresses. But for the manuscripts at Buckingham Palace these operas would be utterly unknown; but Steffani will never cease to be remembered by his beautiful chamber-duets, which, like those of his contemporary Carlo Maria Clari (1669–1745), are chiefly written in the form of cantatas for two voices, accompanied by a figured bass The British Museum (Add. MSS. 5055 seq.) possesses more than a hundred of these charming compositions, some of which were published at Munich in 1679. Steffani visited Italy for the last time in 1727, in which year Handel, who always gratefully remembered the kindness he had received from him at Hanover, once more met him at the palace of Cardinal Ottoboni in Rome. This was the last time the two composers were destined to meet. Steffani returned soon afterwards to Hanover, and died on the 12th of February 1728 while engaged in the transaction of some diplomatic business at Frankfort.

Steffani stands somewhat apart from contemporary Italian composers (*e.g.* Alessandro Scarlatti) in his mastery of instrumental forms. His opera overtures, &c., show a remarkable combination of Italian suavity with a logical conciseness of construction which is due to French influence. In vocal music he is certainly inferior to Scarlatti, and none of his famous duets, despite their charm, can compare for seriousness of intention with the Sicilian's master's chamber-cantatas. His instrumental music, however, is historically important as a factor in the artistic development of Handel.

STEFFENS, HENRIK (1773–1845), German philosopher, scientist and poet, of Norwegian extraction, was born on the 2nd of May 1773 at Stavanger, and died in Berlin on the 13th of February 1845. At the age of fourteen he went with his parents to Copenhagen, where he studied theology and natural science. In 1796 he lectured at Kiel, and a year later went to Jena to study the natural philosophy of Schelling. He went to Freiberg in 1800, and there came under the influence of Werner. After two years he returned to Copenhagen, but his lectures excited so much disapproval that he took a professorship at Halle in 1804. During the War of Liberation he served as a volunteer in the cause of freedom, and was present at the capture of Paris. From 1811 he was professor of physics at Breslau until 1832, when he accepted an invitation to Berlin. Steffens was one of the so-called Philosophers of Nature, a friend and adherent of Schelling and Schleiermacher. More than either of these two thinkers he was acquainted with the discoveries of modern science, and was thus enabled to correct or modify the highly imaginative speculations of Schelling. He held that, throughout the scheme of nature and intellectual life, the main principle is Individualization. As organisms rise higher in the scale of development, the sharper and more distinct become their outlines, the more definite their individualities. This principle he endeavoured to deduce from his knowledge of geology, in contrast to Lorenz Oken, who developed the same theory on biological grounds. The influence of his views was considerable. Not only did Schelling and Schleiermacher modify their theories in deference to his scientific deductions, but the intellectual life of his contemporaries was considerably affected. His lectures in Copenhagen in 1802 were attended by many leading Danish thinkers, such as Oehlenschläger and Grundtvig. Schleiermacher was so much struck by their excellence that he endeavoured, unsuccessfully, to obtain for Steffens a chair in the new Berlin University in 1804, in order that his own ethical teachings should be supported in the scientific department.

His chief scientific and philosophical works are: *Beiträge zur innern Naturgeschichte der Erde* (1801); *Grundzüge der philos. Naturwissenschaft* (1806); *Anthropologie* (1824). He wrote also *Ueber die Idee der Universitäten* (1835), and *Ueber geheime Verbindungen auf Universitäten* (1835); works on religious subjects, *Karikaturen des Heiligsten* (1819–1821); *Wie ich wieder Lutheraner wurde und was mir das Luthertum ist* (1831); *Von der falschen Theologie und dem wahren Glauben* (new ed., 1831); poetical works, *Die Familien Walseth und Leith* (1827); *Die vier Norweger* (1828); *Malcolm* (1831), collected in 1837 under the title of *Novellen*. During the last five years of his life he wrote an autobiography, *Was ich erlebte*, and after his death was published *Nachgelassene Schriften* (1846). See Tietzen, *Zur Erinnerung an Steffens*; Petersen, *Henrik Steffens* (Ger. trans., 1884); Dilthey, *Leben Schleiermachers*.

STEIBELT, DANIEL (*c.* 1764–1823), German pianist and composer, was born at the earliest in 1764 or 1765 in Berlin. He was indebted to the crown prince Frederick William for his musical education. Very little is known of his artistic life before 1790, when he settled in Paris and attained great popularity as a *virtuoso* by means of a pianoforte sonata called *La Coquette*, which he composed for Queen Marie Antoinette; his dramatic opera entitled *Roméo et Juliette*, produced at the Théâtre Feydeau in 1793, was equally successful. In 1796 Steibelt removed to London, where his pianoforte-playing attracted great attention. In 1798 he produced his concerto (No. 3, in E flat) containing the famous "Storm Rondo"—a work that ensured his popularity. In the following year Steibelt started on a professional tour in Germany; and, after playing with some success in Hamburg, Dresden, Prague and Berlin, he arrived in May 1800 at Vienna, where he challenged Beethoven to a trial of skill. His discomfiture was complete and he retired to Paris. During the next eight years he lived alternately in that city and in London. In 1808 he was invited by the emperor Alexander to St Petersburg, succeeding Boieldieu as director of the royal opera in 1811. Here he resided in the enjoyment of a lucrative appointment until his death on the 20th of September 1823.

Besides his dramatic music, Steibelt left behind him an enormous number of compositions for the pianoforte. His playing, though brilliant, was wanting in the higher qualities which characterized that of his contemporaries, John Cramer and Muzio Clementi; but he was gifted with talents of a high order, and the reputation he enjoyed was fully deserved.

STEIN, CHARLOTTE VON (1742–1827), the friend of Goethe, was born at Weimar on the 25th of December 1742, the eldest daughter of the Hofmarschall (master of the ceremonies) von Schardt. She became in her sixteenth year lady-in-waiting to the duchess Anna Amalia, the accomplished mother of Duke Karl August of Saxe-Weimar. In 1764 she married Freiherr Friedrich von Stein, master of the horse to the duke, and seven children were the issue of the union. Goethe, who arrived in Weimar in 1775, was soon captivated by the charm of this lady, his senior by seven years, and the *Seelenbund* (union of souls) they formed exercised a furthering and ennobling influence upon Goethe's life and work. For more than ten years Charlotte von Stein was his constant companion, and by her bright and genial nature and friendship she stimulated his efforts and assuaged his cares. On Goethe's return from Italy in 1788 the previous intimate relations between them were relaxed, and the poet's connexion with Christiane Vulpius still further estranged them. Charlotte's jealousy and indignation at first knew no bounds, and it was only by slow degrees that friendship was restored. Charlotte von Stein was also intimate with Schiller and his wife, and numerous interesting letters from her are to be found in *Charlotte von Schiller und ihre Freunde* (vol. ii., 1862). She became a widow in 1793, but continued to live at Weimar until her death there on the 6th of January 1827.

Goethe's letters to Frau von Stein form one of the most interesting volumes of the poet's correspondence. Her own letters addressed to him were returned to her at her request and destroyed shortly before her death. A prose tragedy, *Dido*, written by her in 1792 (published 1867), is of little poetical value.

Goethe's *Briefe an Frau von Stein aus den Jahren 1776–1820* were edited by A. Schöll (3 vols., 1848–1851; 2nd ed. by W. Fielitz, 1883–1885; 3rd ed., by J. Wahle, 1900). See H. Düntzer, *Charlotte von Stein* (2 vols., 1874); id., *Charlotte von Stein und Corona Schröter* (1876); G. H. Calvert, *Charlotte von Stein* (Boston and New York, 1877); and A. Sauer, *Frauenbilder aus der Blütezeit der deutschen Literatur* (1885); W. Bode, *Charlotte von Stein* (1910).

STEIN, HEINRICH FRIEDRICH KARL, Baron vom und zum (1757–1831), German statesman, was born at the family estate near Nassau, on the 26th of October 1757. He was the ninth child of Karl Philipp, Freiherr vom Stein; the maiden name of his mother was von Simmern. His father was a man of stern and irritable temperament, which his far more famous son inherited, with the addition of intellectual gifts which the father entirely lacked. The family belonged to the order of imperial knights of the Holy Roman Empire, who occupied a middle position between sovereign princes and subjects of the empire. They owned their own domains and owed allegiance only to the emperor, but had no votes for the diet. In his old age he expressed his gratitude to his parents for "the influence of their religious and truly German and knightly example." He added, "My view of the world and of human affairs I gathered as a boy and youth, in the solitude of a country life, from ancient and modern history, and in particular I was attracted by the incidents of the eventful history of England." The influence of English ideas, which was so potent a factor in the lives of Voltaire, Rousseau, Talleyrand and many others in the 18th century, was therefore potently operative in the early career of Stein. He does not seem to have gone to any school; but in 1773 he went with a private tutor to the university of Göttingen in Hanover, where he studied jurisprudence, but also found time to pursue his studies in English history and politics, whereby, as he wrote, "my predilection for that nation was confirmed." In 1777 he left Göttingen and proceeded to Wetzlar, the legal centre of the Holy Roman Empire, in order to see the working of its institutions and thereby prepare himself for the career of the law. Next, after a stay at each of the chief South German capitals, he settled at Regensburg (Ratisbon) in order to observe the methods of the Imperial diet. In 1779 he went to Vienna, gave himself up to the gay life of that capital, and then proceeded to Berlin early in 1780.

There his admiration for Frederick the Great, together with his distaste for the pettiness of the legal procedure at Wetzlar, impelled him to take service under the Prussian monarch. He was fortunate in gaining an appointment in the department of mines and manufactures, for at the head of this office was an able and intelligent administrator, Heinitz, who helped him to master the principles of economics and civil government. In June 1785 he was sent for a time as Prussian ambassador to the courts of Mainz, Zweibrücken and Darmstadt, but he soon felt a distaste for diplomacy, and in 1786–1787 he was able to indulge his taste for travel by a tour in England, where he pursued his researches into commercial and mining affairs. In November 1787 he became Kammerdirektor, *i.e.* director of the board of war and domains for the king's possessions west of the river Weser; and in 1796 he was appointed supreme president of all the Westphalian chambers dealing with the commerce and mines of those Prussian lands. Among the benefits which he conferred on these districts, one of the chief was the canalization of the river Ruhr, which thenceforth became an important outlet for the coal of that region. He also improved the navigation of the Weser, and kept up well the main roads committed to his care. On the 8th of June 1793 he married the countess Wilhelmine, daughter of Field Marshal Count Johann Ludwig von Wallmoden-Gimborn, a natural son of King George II. of Great Britain.

Stein's early training, together with the sternly practical bent of his own nature, made him completely impervious to the enthusiasm which the French Revolution had aroused in many minds in Germany. He disliked its methods as an interruption to the orderly development of peoples. Nevertheless he carefully noted the new sources of national strength which its reforms called forth in France.

Meanwhile Prussia, after being at war with France during the years 1792–95, came to terms with it at Basel in April 1795, and remained at peace until 1806, though Austria and South Germany continued the struggle with France for most of that interval. Prussia, however, lost rather than gained strength at this time; for Frederick William III., who succeeded the weak and sensual Frederick William II. in November 1797, was lacking in foresight, judgment and strength of character. He too often allowed public affairs to be warped by the advice of secret and irresponsible counsellors, and persisted in the policy of subservience to France inaugurated by the treaty of Basel. It was under these untoward circumstances that Stein in 1804 took office at Berlin as minister of state for trade. He soon felt constrained to protest against the effects of the Gallophil policy of the chief minister, Haugwitz, and the evil influences which clogged the administration. Little, however, came of Stein's protests, though they were urged with his usual incisiveness and energy. Prussian policy continued to progress on the path which led to the disaster at Jena (Oct. 14, 1806).

The king then offered to Stein the portfolio for foreign affairs, which the minister declined to accept on the ground of his incompetence to manage that department unless there was a complete change in the system of government. The real motive for his refusal was that he desired to see Hardenberg take that office and effect, with his own help, the necessary administrative changes. The king refused to accept Hardenberg, and, greatly irritated by Stein's unusually outspoken letters, dismissed him altogether, adding that he was "a refractory, insolent, obstinate and disobedient official." Stein now spent in retirement the months during which Napoleon completed the ruin of Prussia; but he saw Hardenberg called to office in April 1807 and important reforms effected in the cabinet system. During the negotiations at Tilsit, Napoleon refused to act with Hardenberg, who thereupon retired. Strange to say, the French emperor at that time suggested Stein as a possible successor. No other strong man was at hand who could save the ship of state; and on the 4th of October 1807 Frederick William, utterly depressed by the terrible terms of the treaty of Tilsit, called Stein to office and entrusted him with very wide powers.
